**Photo 3** Scale on boiler tubes.

of phosphates, chelants, and/or organic polymers. Iron and combinations of iron with calcium and phosphate can form sticky, adherent sludge deposits in boilers and is caused by iron in the form of iron oxide or iron carbonate corrosion products, entering the boiler with the feedwater. It is a result of corrosion products from the sections prior to the boiler, such as steam and condensate lines, condensate receivers, deaerators, and boiler feedwater lines. Modification of the water-side environment may include the use of amine-based corrosion inhibitors added to the steam or condensate,

which generally also neutralize carbonic acid in the condensate and raise the condensate pH.

Foulants in steam boilers usually consist of foreign contaminants present in the feedwater, including muds, oils, contaminants from a process, iron corrosion products from the steam system, and construction debris in new boiler systems. Mud or sludge in a boiler is usually a result of scale-forming minerals combining with iron oxide corrosion products and treatment chemicals, and are commonly controlled by using modern polymeric dispersants, which prevent adherence on heat-transfer surfaces.

In heating boilers, the most frequent foulants (other than sludge) are oil and clay. Oil can enter a boiler system through leakage at lubricators, fuel oil preheaters, or steam heating coils in fuel oil storage tanks. When oil enters a boiler it causes priming and foaming by emulsifying with the alkaline boiler water. Priming is the severe bouncing of the water level that eventually cuts the boiler off at low-water because of the wide fluctuation of this water level sensor. Oil can also carbonize on hot boiler tubes, causing not only serious corrosion from concentration corrosion cells but also tube ruptures as a result of overheating because of insulating carbon deposits and a departure from nucleate boiling (DNB). Whenever oil enters a boiler system, it must be removed immediately to prevent these problems. Modification of the boiler water system environment is usually done by blowing down the boiler heavily

and often by additionally ‘boiling out’ with an alkaline detergent cleaner.

Clay is a less frequent foulant in heating boilers, but it can also form insulating deposits on tube surfaces. Clay enters a boiler with the boiler makeup water that is either turbid or contaminated with excessive alum, used as a coagulant in the clarification process, and has not been subject to filtration or any other makeup water pretreatment process. It can get dispersed during the use of chemical dispersants in the internal treatment of the boiler, but makeup water should be clear and free of any turbidity before it is used as boiler feedwater. Where turbidity and clay are a constant problem, modification of the boiler feedwater by filtration is required (An example is multimedia filtration).

#### 4.27.6.2 Problems due to Mineral Scales, Muds, and Sludges in Cooling Systems

Scale deposits in recirculating cooling tower condenser water systems for HVAC air conditioning and refrigeration chillers are typically a direct result of precipitation of calcium carbonate, calcium sulfite, or silica minerals, because of an overconcentration of these minerals in water. The solubility or pH of saturation is exceeded and the minerals come out of solution. What a heat transfer equipment operator might commonly refer to as ‘scale’ can also include various corrosion products and foulants such as organic matter and mud or dirt.

**Photo 4** shows an example of scaled and corroded condenser tubes.

Modification of the water circuit to prevent mineral scale should, therefore, include the following:

1. Sufficient dilution of the recirculating water to prevent the concentration of minerals from approaching the saturation point.
2. pH control to prevent the pH from reaching the pH of saturation of calcium carbonate.
3. Chemical treatments to inhibit and control scale crystal formation.

In addition to mineral scale, other recurrent problems in recirculating water systems include mud, dirt, debris, foreign matter, and organic growth – especially algae (in warm and sunny weather) and planktonic and sessile bacteria. Deposits of foreign matter plug narrow passages and interfere and foul heat-transfer surfaces, causing inefficient performance of the equipment and energy consumption higher than desirable.

**Photo 4** Scaled and corroded condenser tubes.

A cooling tower is a natural air washer with water spraying over slats and tower fill, and washing the air blown through either naturally or assisted by fans. Depending on the location, all sorts of airborne dust and debris end up in cooling tower recirculating water systems. These vary from fine dust particles to pollen, weeds, plant life, leaves, tree branches, grass, soil, and stones. The fine particles of dust and dirt tend to collect and form a compacted layer in the condenser water system, especially in areas of low circulation and at heat-transfer surfaces. Minimizing these problems again requires modification of the specific waterside environment. It may call for a side-stream filter, screens to limit air-blown dust (say near a construction site), or the regular use of polymeric dispersing chemicals, antiscalents, biocides, and biodispersants.

#### 4.27.6.3 Problems due to Mineral Scales, Muds, and Sludges in Closed-Loop Water Systems

Closed-loop systems contain a finite volume of water and evaporative processes do not take place, although minor water losses because of leaks will occur. Closed-loop systems will include engines under circumstances where they are employed in emergency/backup electricity generating systems and similar applications (e.g., standby diesel generators for hospitals, commerce, and general industry, and diesel engine utility power generators). Some closed-loop systems are not in fact ‘closed’ and may have, for example, a returned water receiver that channels a number of individual cooling water lines to a single point before being pumped across a heat-exchanger and around another loop.

As a general rule, all closed and semi-closed loop systems tend to suffer to some extent or other from iron and steel corrosion problems because of the prolific use of mixed metals, poor passivation, and limited maintenance. Therefore, one of the most common and difficult foulants found in closed systems is a black mud made up of compacted, fine, black magnetic iron oxide particles, which deposit at heat-transfer surfaces, and clog or block narrow passages in unit heaters, fan coil units, and cooling, reheat, and heating coils in air-handling units. This mud is a result of very fine wet particles of black magnetic iron oxide compacted into a dense adherent mud.

The interior of black iron piping, commonly used for recirculating water, has a natural black iron oxide protective coating ordinarily held intact by oil-based inhibitors used to coat the pipe to prevent corrosion during storage and lay-up. This natural iron oxide protective coating is called mill scale, a very general term which can be applied to any form of pipe scale or filings washed off the interior of the pipe. This mill scale film becomes disturbed and disrupted during construction because of the constant rough handling, cutting, threading, and necessary battering of the pipe. After construction, the recirculating water system is filled and flushed with water, which removes most of the loosened mill scale along with other construction debris. However, very fine particles of magnetic iron oxide will continue to be washed off the metal surface during operation, and in many instances this washing persists for several years before it subsides. Mill scale plugging can be a serious problem. It is best alleviated in a new system by thorough cleaning and flushing with a strong, low-foaming detergent-dispersant cleaner. This, however, does not always solve the problem. Even after a good cleanout, gradual removal of mill scale during ensuing operation can continue.

#### **4.27.6.4 Problems due to Waterside-Surfaces Fouling in 'New Construction' HVAC Systems**

All new HVAC systems can become fouled and contaminated with various forms of foreign matter during construction. It is not uncommon to find remnants of welding rods, beads, paper bags, plastic wrappings, soft drink can rings, pieces of tape, insulation wrappings, glass, etc. in the interior of HVAC piping and heat exchangers. Also, cement, mortar, metal filings, pieces of pipe, and other construction debris may be present. Oil and mill scale is usually

found and can seriously foul and plug closed systems, and cause boiler tube failures if the oil is carbonized during firing. It should be noted that commonly found black iron pipe 'scale' is not, in fact, a mineral scale, but rather the oxides of iron (rust) produced during manufacture and storage. It is also called mill scale and can be slightly protective to the pipe against contaminants in water, but is not sufficiently nonporous for good protection.

It is necessary not only to clean out construction debris from the interior of new construction HVAC systems prior to initial operation, but also to modify the waterside environment by cleaning the metal surfaces of oil and mill scale naturally present on the pipe interior, then passivate the metal surface, and follow up with an initial feed of inhibitor chemicals. Cooling water systems and boiler must be cleaned thoroughly with an alkaline detergent-dispersant type of cleaner. Where the boiler is a steam raising plant, an alkaline boilout compound is used. All this takes place before implementing a maintenance chemical treatment and technical service overseeing program.

#### **4.27.6.5 Problems due to Mineral Scales, Muds, and Sludges in Potable Water Lines**

Water containing unusual turbidity or suspended matter is usually treated at the source by coagulation, clarification, and filtration so as to improve its quality. Turbidity is the cloudiness or haziness of a fluid caused by individual particles (suspended solids) that are generally invisible to the naked eye, similar to smoke in air. The measurement of turbidity is a key test of water quality. However some minor level of turbidity may still be present that will be acceptable if it does not affect potability. Therefore, the presence of excess levels of suspended matter and turbidity is not common in makeup waters to HVAC systems as the makeup water usually comes from a municipal or local source, over which there is an authority responsible for delivery of clear, potable quality water.

Where private well water and pond, or other non-public sources of water are available for use as makeup water to cooling water systems and boilers, it should be carefully examined for turbidity and suspended matter. Governments around the world have set standards for the allowable turbidity in drinking water. In the United States, the allowable standard is 0.3 NTU, with many utilities striving to achieve levels as low as 0.1 NTU.<sup>12</sup> When the supply is excessively turbid, modification by some form of

clarification should be used to remove the suspended matter and reduce the turbidity to below 1 NTU. Modification examples include coagulation, settling, filtration, and/or fine strainers.

The more common problem with suspended matter and turbidity results from makeup water that is temporarily or occasionally dirty, which may occur when the local water authority is cleaning sections of a distribution main, installing new mains, or when water mains are cut into during some nearby construction project. These deposits consist mostly of iron oxide corrosion products and dirt, clay, or silt.

#### 4.27.7 Problems of Corrosion including Microbial Induced Corrosion

Corrosion occurs very rapidly in heat-transfer equipment because of the presence of heat, corrosive gases and dissolved minerals in water, which stimulate the corrosion process. Corrosion mechanisms can be concentrated locally to form a pit or crack, or under local environmental conditions, extend across a wide area to produce general deterioration. The local corrosive conditions may be caused by use of dissimilar metals, excess of oxygen, short- or long-term stress (such as that at points of welds, bends, and elbows), and excessive or prolonged heat, or thermal shock.

Although specific corrosion problems, such as the various types of differential aeration mechanisms, hydrogen embrittlement, and flow assisted/accelerated corrosion (FAC) – especially in high-pressure utility boilers and heat recovery steam generator (HRSG) plants – can take place the most common forms of corrosion found in heat-transfer equipment include the following:

- uniform or general corrosion;
- oxygen pitting corrosion;
- galvanic corrosion;
- concentration cell or crevice corrosion;
- stress corrosion;
- erosion corrosion or impingement corrosion;
- condensate line corrosion or grooving corrosion;
- microbiologically influenced corrosion (MIC); and
- white rust.

In water systems, modification of a waterside environment to minimize corrosion will involve direct or indirect passivation of a metal surface, a change in pH, and use of oxygen scavengers (in boiler plants), and usually require small concentrations of corrosion inhibitors (especially in cooling systems).

#### 4.27.7.1 Uniform or General Corrosion

General corrosion is found in various forms in HVAC and other heat-transfer equipment and can be seen as an overall deterioration of the metal surface, with an accumulation of rust and corrosion products in the piping and water boxes. For example, it might be present as a surface gouging or a uniform thinning of the tube metal on copper condenser tubes, or in boilers, as the total overall disintegration of a boiler tube metal surface in contact with boiler water.

This type of corrosion occurs when the process takes place over the entire surface of the metal, resulting in a uniform loss of metal rather than a localized type of attack. Iron and other metals are corroded by electrochemical reaction resulting in the metal going into solution in the water. The waterside environment will usually have some level of oxygen present, plus possibly dissimilar metals or areas of stress, together with dirt, and/or an accumulation of corrosion products over the surface of the metal. It is necessary, therefore, to limit corrosion of these metals by cleaning the system, passivating the metal surface, and by reducing the activity of both hydroxyl ions and hydrogen ions, that is, by developing a corrosion-free environment through the use of corrosion inhibitors.

#### 4.27.7.2 Oxygen Pitting Corrosion

An important factor in corrosion processes is dissolved oxygen, and it may manifest itself in various forms of differential aeration corrosion and under-deposit corrosion processes, producing tubercles or other accumulations of rust and corrosion products. Specifically, oxygen pitting is characterized by deep penetration of the metal at a small area on the surface with no apparent attack over the entire surface, as in general corrosion. The corrosion takes place at a particular location on the surface and corrosion products frequently accumulate over the pit. These appear as a blister, tubercle, or carbuncle.

Localized pitting corrosion is a common problem and may result from a variety of contributory causes, such as deposits of foreign matter. However oxygen pitting corrosion differs somewhat from other forms of pitting corrosion in that it is caused solely by the presence of dissolved oxygen, which reacts with a metal, eventually forming the insoluble oxide and builds up a voluminous deposit of rust in the case of iron and steel.

**Photo 5** shows an example of oxygen pitting corrosion in a sectioned length of boiler pipe.

**Photo 5** Oxygen pitting corrosion.

In boilers, oxygen pitting occurs where the feedwater contains dissolved oxygen. The pitting is found on boiler tubes adjacent to the feedwater entrance, throughout the boiler, or in the boiler feedwater line itself. Modification of the feedwater often entails mechanical deaeration through the use of a vacuum or pressure deaerator. However, oxygen pitting can still develop in boiler feedwater lines following a deaerator, as low concentration of dissolved oxygen can be more corrosive in feedwater than higher dissolved oxygen content! Mechanical deaerators are not 100% efficient and none can produce a feedwater with zero oxygen. The lowest guaranteed dissolved oxygen content that deaerators produce is  $0.005 \text{ cm}^3 \text{ l}^{-1}$ . This trace quantity of dissolved oxygen is sufficient to cause severe pitting in feedwater lines or in boiler tubes adjacent to the feedwater entrance. In this situation, oxygen pitting is characterized by deep holes scattered over the surface of the pipe interior with little or no accumulation of corrosion products or rust, as there is insufficient oxygen in the environment to form the ferric oxide rust.

However, in utility peaking boilers or in cyclic operations, it may, in fact, be necessary to modify the waterside environment by adding a constant trace amount of oxygen (oxygenation treatment, OT) in order to maximize the maintenance of a protective magnetite film on the metal surface at the metal/water interface, and minimize the development of excessive quantities of corrosion product debris ('crud').

#### 4.27.7.3 Galvanic Corrosion

Galvanic corrosion (dissimilar-metal corrosion) is an electrochemical process in which one metal corrodes preferentially, when in electrical contact with a

different type of metal, and both metals are immersed in an electrolyte such as water. Typically in an industrial process water system or HVAC system, different metals of construction will be used, and more often than not they are not dielectrically insulated from each other, but are connected via a flange, valve, union, or brazed joint. Thus, when the two or more different types of metal come into contact with one another (as in the coupling of steel and copper in a heat-exchanger), a galvanic couple is set up, as the different metals have different electrode potentials. The electrode potential is the tendency of a metal to give up electrons and go into solution.

The system water electrolyte provides a means for ion migration, whereby metallic ions can move from the anode to the cathode. This leads to the anodic metal corroding more quickly than it otherwise would; the corrosion of the cathodic metal is retarded even to the point of stopping. The presence of electrolyte and a conducting path between the metals may cause corrosion, where otherwise neither metal alone would have corroded. Also, a single type of metal may corrode galvanically if the electrolyte varies in composition, forming a concentration cell.

The rate of galvanic corrosion is strongly influenced by the electrode potential difference between the dissimilar metals. The galvanic series is a list of metals in order of their activity, the most active being at the top of the list and the least active at the bottom. The further apart two metals are on this list, the greater will be the reactivity between them and, therefore, the faster the anodic end will corrode.

Methods for the modification of the waterside environment to control the rate of active galvanic corrosion include the following:

1. Eliminating the contact of dissimilar metals in an HVAC system by using insulating couplings or joints such as a dielectric insulator coupling, which interferes with the electron flow from one metal to the other.
2. Eliminating one or more of the essential elements required for galvanic corrosion to occur. This might require, for example, modifying the HVAC system design by changing one of the metallic materials of construction, such as zinc or copper.
3. The use of protective coatings and chemical corrosion inhibitors, which all provide a physical or chemicochemical barrier between the corroding metal and its environment.

#### 4.27.7.4 Concentration Cell Corrosion or Crevice Corrosion

Concentration cell corrosion, like pitting corrosion, is a localized type of differential aeration corrosion rather than a uniform attack. It is a form of under-deposit corrosion or crevice corrosion, as it occurs under deposits or at crevices of a metal joint. Differential aeration cells can be caused by crevices, lap joints, deposits of foreign matter, dirt, organic matter, corrosion products, scale, construction debris, and moist insulation. Oxygen not only enables a corrosion reaction by maintaining a cathodic reaction, but it can promote one where there is a difference in the concentration of dissolved oxygen between two points of the same metal surface.

If the supply of oxygen is not uniform across a surface, then any regions that are depleted in oxygen will become anodic, for example within a crevice, at a joint or beneath a surface deposit. The remainder of the surface with free access to oxygen acts as a large cathodic area. Thus, where there is a difference in the concentration of dissolved oxygen at two points on a metal surface, the surfaces in contact with the solution containing the higher concentration of dissolved oxygen will become cathodic to surfaces in contact with a lower concentration of dissolved oxygen. Because the cathodic area is so much larger, severe local attack will occur in the small anodic region.

Additionally, where contaminants (such as chlorides or sulfates) are present in the water, these can concentrate under the deposit or in the crevice and rapidly increase the rate of corrosion – leading to gouging corrosion or pitting corrosion, where the anode will again suffer accelerated corrosion in the (oxygen) concentration cell. Thus, the rate of supply of oxygen or ion concentration will govern the rate and mechanism of rusting. With concentration cell corrosion, the corrosion reaction proceeds as in galvanic corrosion, as this differential also forms an electrode potential difference. Maintaining clean surfaces, in conjunction with chemical inhibitors can best prevent this form of corrosion.

In closed-loop systems where the water is, in fact, not closed but in contact with air (as in many plastic extrusion component manufacturing facilities, where various cooling water streams flow to a common receiving tank) concentration cells can develop and severe crevice corrosion can occur. Limiting contact with oxygen in the air by use of a physical barrier, such as a floating plastic sheet, is an

option, but system modification will still require the addition of anodic or cathodic inhibitors to the water.

#### 4.27.7.5 Stress Corrosion

Stress corrosion failure is a result of a corrosive environment and stresses and strains at the very point of failure. It is because of the combination of exposure of a metal to a corrosive environment and the application of stress on the metal, such as in stress-corrosion-cracking mechanisms involving various grades of stainless steel, where the alloy comes into contact with a corrosive, high-chloride concentration environment. It can also occur on condenser tubes and heat-exchanger tubes, from heat expansion that causes stresses in the metal at tube supports or tube sheets.

Stress corrosion is frequently seen on condenser tubes and boiler tubes in the area where the tubes are rolled into the tube sheets. In steam boilers, stress corrosion has been referred to as ‘necking and grooving.’ It is also seen as a circumferential groove around the outside of a firetube in a firetube boiler, where it enters the tube sheet. Usually it occurs at the hottest end of the tube, (i.e., at the beginning of the first pass against the firewall). Stress corrosion concentrates at the tube end because of strains from two sources. First, when tubes are rolled in, stresses are placed on the metal, expanding the metal to fit the tube sheet (and the stresses may be unrelieved). Second, when a boiler is fired, the heat causes rapid expansion of the tube, and consequently strains are greatest at the tube ends, which are fixed in the tube sheets. This actually causes a flexing and bowing of the tube, and sometimes the expansion is so severe that the tubes loosen in the sheets. During this bending of the tube, the natural protective iron oxide film formed at the tube ends tends to tear or flake off, exposing fresh steel to further attack. Eventually, the tube fails because of a combination of both corrosion and stress.

Reducing the risk of stress-corrosion in stainless steel alloys (and other types of alloy) starts with improved product selection and design. Also, it requires the removal or modification of the corrosive waterside environment – often through regular cleaning practices and the use of inhibitors. The problem of stress corrosion in boilers is reduced by more gradual firing practices, and by using proper inhibitors to correct the corrosive environment.

#### 4.27.7.6 Erosion Corrosion or Impingement Corrosion

Erosion corrosion or impingement corrosion is the gradual wearing away of a metal surface by a combination of both corrosion and abrasion from an impinging water stream, such that the higher the velocity of the impinging stream, the greater the rate of erosion corrosion. Water moving rapidly through piping can contain entrained air bubbles and suspended matter, sand, or other hard particulates. These abrasive particles remove natural protective oxide films present on the surface of the metal and cause general corrosion of the exposed metal.

Unfortunately, this is not uncommon in cooling tower waters where such particles are extracted from the atmosphere so that in environments where high levels of particulates can enter the system (e.g., close to a construction site or in an open area where high winds are prevalent), modification of the water treatment program usually calls for the installation of a side-stream or fill-stream filter, plus perhaps a dispersant chemical.

A special kind of erosion corrosion that has become very prevalent in recent times, with the increased use of cogeneration and combined cycle power plants that utilize heat recovery steam generators (HSRG), is flow assisted or flow accelerated corrosion (FAC). FAC is a term originating with The Electric Power Research Institute (EPRI) for a condition that the industry has previously labeled with the more generic term erosion corrosion. EPRI defines FAC as “a process whereby the normally protective oxide layer on carbon or low-alloy steel dissolves into a stream of flowing water or a water–steam mixture.” It can occur in single phase and in two phase regions. EPRI has stated that the cause of FAC is water chemistry.<sup>13</sup>

Several variables contribute to this phenomenon including but not limited to velocity, pH, directional changes and geometry, temperature, chemistry, oxygen concentration, oxygen scavenger (reducing environment), and material composition. Two phase FAC can be differentiated from cavitation erosion by the evidence of ‘tiger stripes’ or ‘chevrons.’

*Note:* Cavitation erosion (CE) occurs downstream of a directional change, or in the presence of an eddy. Evidence can be seen by the presence of round pits and is often misdiagnosed as FAC. Like erosion, CE involves fluids accelerating over the surface of a material; however, unlike erosion, the actual fluid is not doing the damage. Rather, cavitation results from

small bubbles in a liquid striking a surface. Such bubbles form when the pressure of a fluid drops below the vapor pressure, the pressure at which a liquid becomes a gas. When these bubbles strike the surface, they collapse, or implode. Although a single bubble imploding does not carry much force, over time, the small damage caused by each bubble accumulates. The repeated impact of these implosions results in the formation of pits. Also, like erosion, the presence of chemical corrosion enhances the damage and rate of material removal. Cavitation is not a property of the material, but a property of the system itself. The fluid pressure is determined by the size and shape of the vessel, not the material. While a stronger material can be highly resistant to cavitation, no metal is immune.<sup>14</sup>

#### 4.27.7.7 Condensate Line Corrosion or Grooving Corrosion

Condensate corrosion or grooving corrosion is a particular, but very common, corrosion phenomenon of steam condensate lines in HVAC and industrial process equipment. The primary cause of condensate grooving is carbon dioxide. The dissolved carbon dioxide is a breakdown product of calcium bicarbonate in boiler feedwater – originating from the makeup water component of feedwater. The CO<sub>2</sub> gas is volatile and carries over with the generated steam in the boiler, then dissolves in the hot condensate, forming carbonic acid. Typically the pH of condensate may fall to perhaps as low as 5.5 or 6.0.

Condensate corrosion is found in steam condensate piping on all types of equipment, heat exchangers, steam-turbine condensers, unit heaters, steam absorption condensers, radiators, or any type of unit utilizing steam as a heat-transfer medium. It is a direct chemical attack by acidic steam condensate on the metal over which it flows, and is identified by the typical grooves found at the bottom of the pipe carrying the condensate.

The methods available to prevent this type of corrosion include removal of bicarbonate and carbonate alkalinity from the boiler makeup water (dealkalization) and use of carbonic acid neutralizers and filming inhibitors.

Usually, these inhibitors are amine-based. Food industries tend not to use amine-based corrosion inhibitors, for fear of odors or taints they may impart to the food in question; therefore, they may use sorbates and other inhibitors of similar chemistry — which, although ‘safe’ are not particularly effective,

despite claims to the contrary. Often, the food company will prefer to suffer the consequences of condensate line corrosion rather than spent capital on a dealkalization plant or use amine inhibitors, some of which are permitted in the United States for the food manufacturing industry at certain maximum concentrations, under Code of Federal Regulations (CFR), §21, section 173.310.

#### 4.27.7.8 Microbiologically Influenced/ Induced Corrosion or Biocorrosion

The term ‘microbiologically influenced corrosion’ covers a wide range of corrosion processes that are initiated or promoted by microorganisms – usually chemoautotrophic bacteria (i.e., bacteria that obtain energy by the oxidation of electron-donating molecules in their environments). MIC is a very serious problem in all types of industry, affecting, for example, buried water, gas, and oil pipelines, as well as petroleum products and fuel storage tanks. Attack can take place on both the external and internal metal surfaces, with the microorganism living in the water phase (i.e., microorganisms in the water table can cause MIC on external metal pipeline/tank surfaces, and microorganisms in tank ‘bottoms’ can cause MIC of internal metal pipeline/tank surfaces, as well as damage the stored fuel or other product). Similarly MIC can affect industrial heating and cooling systems, potable water lines, and building HVAC systems. **Photo 6** shows an example of MIC on a section of pipe.

There are many forms and mechanisms of MIC involving many types of microbiological organisms, both aerobic and anaerobic. MIC in water systems can be initiated by various major groups of organisms, and their biomass products (biofilm) such as the following:

- *Iron related bacteria (IRB)*. IRBs include *Gallionella ferrugine* (which oxidizes ferrous ions to ferric ions and manganous ions to manganic ions) and *Ferrobacillus* sp.
- *Sulfate reducing bacteria (SRB)*. The genera *Desulfovibrio*, *Desulfomaculum* and *Desulfomonas* are both anaerobic microorganisms and reduce  $\text{SO}_4^{2-}$  to  $\text{S}^{2-}$  and  $\text{H}_2\text{S}$ .
- *Acid producing bacteria (APB)*. These are mainly slime-forming microorganisms, and include *Acidithiobacillus thiooxidans*, which oxidize sulfur and sulfides to  $\text{H}_2\text{SO}_4$ , and *Acidithiobacillus ferrooxidans* which oxidize ferrous ( $\text{Fe}^{2+}$ ) ions to ferric ( $\text{Fe}^{3+}$ ) ions. Also, APBs include *Pseudomonas*, *Aerobacter*, and *Bacillus* spp. which exude various organic

**Photo 6** MIC on a sectioned pipe.

acids in their metabolic process, resulting in localized underdeposit and pitting corrosion, often resulting in pinholes in pipework.

Apart from bacterial slimes, biomass, or biofilm can be produced by other types of microorganisms, including algae, yeast, molds, and fungus. Slimes and biofilms can provide the environment for corrosion through establishment of concentration cells resulting in under deposit corrosion. Also, biological deposits in general act as traps and food for other organisms resulting in rapid growth. This complex matrix sets up a corrosion potential between adjacent areas of a metal surface that may have a different type of deposit. Additionally, biofilms provide a safe environment for organisms when attacked by biocides, necessitating the additional use of biological penetrants or biodispersants to effect a good kill level in cooling water systems.

To control MIC it is important to understand the organisms and processes that cause it. Modification of the waterside environment will require periodic microbiological testing and use of specific types of microbiocides – usually a tailored program containing both an oxidizer and a nonoxidizer.

#### 4.27.7.9 White Rust Corrosion

Many ‘standard’ cooling water system components, such as HVAC panels, basins, and complete cooling towers, are constructed of galvanized steel for ease of fabrication and low manufacturing costs. Galvanizing produces a zinc–iron intermetallic alloy in layers on a steel surface that acts as a corrosion-resisting coating. The zinc is anodic to steel and thus will provide cathodic or sacrificial protection to any small areas of steel that may be exposed (i.e., scratches, cut edges,

etc.). Also, the passive, oxidized zinc coating provides a physical barrier in protecting the bulk of the steel surface from any direct contact with the environment. However, with the giving up of the use of sulfuric acid and chromate as a water treatment scale and corrosion-inhibiting chemical treatment program in most parts of the world over 30 years ago, a corresponding, and significant rise in white rust corrosion has been observed. It has become such a serious problem, especially in new construction, that many cooling tower manufacturers have turned to using glass fiber and plastics.

White rust corrosion is a problem where the fresh galvanized surface is not able to form a protective, nonporous, basic zinc oxide, especially where the surface is partially wetted or completely submerged in water. Deterioration begins when a localized corrosion cell is formed, leading to pitting corrosion, metal wastage, and reduced equipment life expectancy. White rust corrosion is often identified by the white, gelatinous or waxy deposit of a porous zinc-rich oxide complex,  $3\text{Zn}(\text{OH})_2 \cdot \text{ZnCO}_3 \cdot \text{H}_2\text{O}$ . It is aggravated by the modern use of high-pH, high-alkalinity water chemistries, and in softer waters, especially when appropriate pretreatment passivation protocols have not been followed (a major problem in new construction).<sup>15</sup>

#### 4.27.8 Problems of Microbiological Fouling

All water systems have the potential for the growth of microorganisms, and the production of slimes, biomass, or biofilm, which, not only present fouling and corrosion problems, but can also compromise the health and safety of workers and visitors. In cooling systems, spa baths, potable hot water lines, and calorifiers (hot water generator and storage tanks), the presence of slimes and biofilm can increase the risk of illness from, for example, Legionnaires' disease. **Photos 7(a) and 7(b)** below show microbiological fouling in a cooling system.

As noted earlier, microorganisms to be found in water systems can include not only bacteria, algae, yeast, molds, and fungus, but also unicellular protozoa (such as *Cryptosporidium*, *Paramecia*, and *Amoeba*).

Algal growths and biofilms are always found to some degree in open recirculating water systems such as cooling towers, evaporative condensers, air washers, and spray-coil units. Occasionally closed systems can become fouled with organic slimes

**Photo 7** (a) Algal fouling on a cooling tower and (b) fouled and corroded heat exchanger.

because of foreign contamination (although the single biggest problem here is always corrosion, usually as a result of improper initial cleaning, passivation, and ongoing use of chemical inhibitors).

Open cooling systems are constantly exposed to the atmosphere, and the local environment can contain dust, dirt and innumerable quantities of microscopic organisms such as algal cells and bacteria, which will enter the cooling systems because of the scrubbing of air during the evaporative cooling process. Also, because cooling water is exposed to sunlight, often operates at ideal growth temperatures, and contains nutrients, it provides a favorable environment for the abundant growth of biological organisms. The basic types of microorganisms found in cooling systems, and system environment modification methods are discussed below:

- **Algae.** The types of algae found in open recirculating water systems include the blue-green algae, green

algae, and brown algae. Large masses of algae can cause serious problems by blocking the air in cooling towers, plugging water distribution piping and screens, and accelerating corrosion by concentration cell corrosion and pitting. Algae must be removed physically before a system can be cleaned as the mass will provide a continuous source of material for reproduction and biocides will be consumed only at the surface of the mass, leaving the interior alive for further growth. Modification of the cooling water environment will include screening sunlight from towers by use of distribution trough covers, and the periodic use of specific algaecides, such as tertbutylazine (TBZ).

- *Fungi*. Fungi usually require low alkalinity waters and can grow together with algae, as the algae living within the fungus mass are furnished with a moist, protected environment, while the fungus obtains carbohydrates from the algae. Fungi can attack wood contained in cooling towers, so treated wood is used. Also, biocides such as tris(hydro-methyl)nitromethane (trinitro) may be employed.
- *Bacteria*. There are hundreds, if not thousands, of potential types of bacteria that may be found in water systems, especially cooling water systems. Bacteria are microscopic unicellular living organisms that exhibit both plant and animal characteristics. They may be rod-shaped, spiral, or spherical in shape, and may be pathogenic or harmless to people. However, in general, the most troublesome organisms are the slime producers – iron bacteria, sulfate-reducing bacteria, etc.

Bacteria may be found free-floating in water (planktonic bacteria) and are relatively easy to kill, although persistent strains and rapid regrowth may develop if the kill-rate is not maximized. Bacteria growing within a biofilm (sessile organisms) are more difficult to kill.

In general, the control of microorganisms is undertaken by developing a protocol or program for the selective and periodic (or semicontinuous) addition of oxidizing and/or nonoxidizing pesticides (also called microbiocides or biocides). Nonoxidizing biocides include isothiazolinones, thiones, and gluteraldehyde. Oxidizing biocides include various chlorine and bromine donors, such as bleach, calcium hypochlorite, and dibromohydantoin. Additionally, cationic, anionic, and non-ionic biocides and special biocidal cleaners may be employed.

Monitoring by the use of simple site tests, such as dip-slides, is necessary to establish the concentration of planktonic and sessile organisms, kill rates, and

regrowth rates. Under more difficult cooling water operating conditions, or where there may be resistance to certain pesticides or a reason to suspect the potential for the growth of pathogens, special testing is carried out in a microbiological laboratory.

#### 4.27.8.1 Problems of Amplification of Pathogenic Bacteria

Pathogenic bacteria are disease-causing bacteria. Cooling tower waters and domestic hot water lines in particular, have ideal conditions for the growth of bacteria and other organisms, and can promote the growth of pathogenic strains, which may then give rise to infection and possibly death, for example the amplification of commonly found *Legionella* organisms in cooling water and domestic hot water, leading to the risk of illness from Legionnaires' disease. It is important to keep these systems clean and free of general bacterial contamination in order to inhibit growth of potentially pathogenic bacteria, as well as to prevent corrosion from slime-forming organisms. **Photo 8** shows *Legionella* sp. amplifying in an amoeba.

Disease forming organisms that may grow in water systems that are not regularly cleaned, disinfected, or otherwise maintained may include the following:

- *Legionella pneumophila*, especially serotype 1. Responsible for Pontiac fever and Legionnaires' disease, a potentially fatal type of pneumonia.
- *Mycobacterium avium*. Responsible for nontuberculosis mycobacterium disease, also called hot-tub lung disease.
- *Pseudomonas* sp. Responsible for chronic respiratory infections and infections of the eye, skin, and soft tissue.

**Photo 8** *Legionella* sp. bacteria in an amoeba.

- *Escherichia coli*. Responsible for septicemia and diarrhea.
- *Giardia lamblia*. Responsible for Giardiasis, producing diarrhea and abdominal cramps.

Modification of the waterside environment to prevent bacteria related problems means that all cooling systems should be drained, cleaned, and disinfected at least twice per 12-month period, irrespective of whether the cooling systems operate all year round or only on a summer cycle. Some countries mandate this approach by law. Others demand three cleanings and disinfection programs per year. In addition to good maintenance, a periodic risk assessment and ongoing surveillance program should also be instituted, and all records kept in a logbook. Implementation of a risk assessment program is an additional and necessary precaution for many facilities prior to starting up a new or winterized tower, or where design or location is suspect (e.g., poor drift elimination, or the tower is sited too close to a ventilation system's fresh air intake).

#### **4.27.9 Evaluating and Modifying Waters for Use or Reuse in Industrial Processes and HVAC Water Systems**

Municipally treated waters are of potable quality, but may require some form of treatment, such as reducing or modifying the concentration of minerals, salts, and other compounds present, before becoming suitable for industrial process applications. Surface waters and well waters drawn directly from source will inevitably require pretreatment, and recycled treated waste waters or reused industrial waters will, likewise, require pretreatment, regardless of the process application envisioned.

In general, treatment will take several steps, the first being a basic 'cleanup' using mechanical filtration, ion-exchange water softening, or similar capital intensive process. Next may follow a purification process, such as demineralization by ion-exchange or membrane process, or mechanical deaeration. Finally, an ongoing, maintenance chemical treatment program will be employed for 'polishing' purposes.

Cooling systems are generally accepting of a wide diversity of water sources and provided the water is reasonably consistent in quality, many industrial streams can be economically recovered and reused as tower makeup. However, as noted above, recoverable process waters will always require some measure

of judicious pretreatment before being recycled for reuse in cooling systems, even if it is only to remove particulates, fats, oils, and greases (FOG) and heavy metals; and to make pH adjustments (say pH 7.0–8.5). Water used as a makeup source for steam boilers may need significant pretreatment, depending upon the boiler design and pressure. Generally, as boiler pressure rating increases, the makeup water employed will need to be further modified or 'purified' by removing most, if not all, measurable contaminants.

In industry, water is employed for innumerable applications, not simply for heating and cooling. It is required, for example, in dissolving, washing, cleaning, dyeing, rinsing, melting, quenching, stripping, scrubbing, desalting, plating, surface coatings, fermentation, dust control, process liquors, steam heating, drying, cooking, pasteurization, oil and gas abstraction, and domestic purposes. Additionally, excess water results from distillation, evaporator condensates, reverse osmosis (RO) reject, oil and gas production, boiler blowdown, chemical manufacturing, recovery of fibers and chemicals, straining, filtration, drainage, and a myriad of other process operations. This water may be treated and recycled, or reused for other types of process, or downstream applications.<sup>16,17</sup>

Any water considered for use or reuse in industrial processes and even for small, simple, HVAC water system applications must first be evaluated, if problems of corrosion and scaling are to be avoided or minimized. In general, we would need to consider the following:

1. An understanding of the process flows, operating conditions, materials balance, and volume/quality requirements.
2. A full understanding of the chemistry of the water under consideration, plus testing parameters, limitations, and costs. We need to know the chemical and physical characteristics, including pH, temperature, calcium, magnesium, alkalinity, silica, suspended solids, chlorides, sulfates, and the presence of potentially undesirable constituents, such as FOG, solvents, ammonia, soluble/insoluble iron, and heavy metals. Also, we may need to know the 5-day biochemical oxygen demand (BOD<sub>5</sub>), chemical oxygen demand (COD) or total organic carbon (TOC) analysis.
3. We have to be able to interpret the data, in order to identify which contaminants may provide limiting factors regarding deposition, fouling, or corrosion of materials of construction (such as copper,

steel, heat-exchanger alloys, or concrete), and would thereby impact chemical treatment programs, cycles of concentration (COC), bleed discharge volumes, and ongoing costs.

4. We need to provide a robust and economic pretreatment design, ensuring that the treated water meets the desired or practical/useable/chemical/physical water quality specifications.
5. Where water is used for cooling purposes, we also need to consider further modification of the waterside environment by the operational protocols and the downstream chemical inhibitor treatment program(s) that will be used on a regular maintenance basis.

In order to keep water consumption as low as practically and economically possible, we need to consider COC (i.e., the ratio of concentration of TDSs in recirculating water to that of the make-up water employed). This requires us to consider corrosion, fouling, and deposition risks, as indicated by basic and ionic equilibrium model saturation indices or ion-association predictive modeling (see also [Sections 4.27.13–4.27.15](#)). However, the law of diminishing returns applies for any specific cooling system, beyond a certain COC number, the risk of waterside problems increases greatly as the reward of water savings progressively diminishes. A COC of  $4\times$  to  $6\times$  is often a good standard. There is seldom any significant benefit in raising COC levels to  $>10\times$  unless the water is a lean acid water, with a minimum of minerals and other contaminants present, or a zero liquid discharge (ZLD) system is in place.<sup>16</sup>

#### 4.27.10 Modifying Water by Selective Use of Standard Pretreatment Processes

The types of water contaminant pretreatment process under consideration will depend upon the degree of contaminant removal or modification required. Some examples of pretreatment equipment are shown in [Photos 9\(a\)–9\(d\)](#).

Although certain types and brands of ‘nonchemical devices’ (‘gadgets’) such as magnetic devices (not the same as a magnetic separator), electrostatic, pressure changing, or catalytic devices may be employed, these tend not to have mainstream acceptance. This is usually because of limited availability of peer-reviewed data and/or extravagant claims.

Examples of mainstream, ‘standard’ pretreatment processes include the following:

- *Alkalinity removal.* This process can be carried out via lime softening, sulfuric acid treatment, or ion-exchange dealkalization.

A steam boiler that operates with makeup water containing excessive quantities of carbonate and bicarbonate alkalinity not only will develop excess alkalinity in the boiler (causing priming, foaming, and carryover), but also will generate large quantities of carbon dioxide as a result of decomposition of the carbonates and bicarbonates. This process results in an acid steam and condensate, which, as noted previously, causes severe corrosion of steam and condensate return lines. The alkalinity in these cases can be reduced by 90%, by passing the makeup water through a dealkalizer following the water softener.

The typical dealkalizer plant contains an ion-exchange resin similar to the water softener with the capability of exchanging carbonate, bicarbonate, sulfate, and other anions for chloride, hence the name ‘chloride anion dealkalizer’ (i.e., a strong base anion (SBC) resin in the chloride form). Alternatively the dealkalizer can be a strong/weak acid cation (SAC/WAC) in the hydrogen form, plus degassing. In this type of plant, there is a reduction in dissolved minerals, leading to a reduction in boiler blowdown requirements and thus, energy savings.

- *Dirt, grit, sand, slime, algae removal.* This can be achieved by using a strainer, bag or cartridge filter, sand filter, multimedia filter, inclined plate clarifier (e.g., Lamella Gravity Settler), or conventional coagulation/sedimentation/clarification techniques. It is common practice to install strainers prior to pumps on open recirculating condenser water systems to protect the pump internals, vanes, shaft and impellers from large damaging flakes of rust, suspended dirt, or other foreign particles that can enter an open system. Similarly, strainers should be installed on closed systems as they are frequently plagued with suspended black magnetic iron oxide mill scale as well as foreign particles. The bag or cartridge strainer can be used as a coarse filter to remove larger particles before the pumps and heat exchangers.
- *Disinfection.* Here, we might consider ultraviolet light at 254 nm (UV), ozone, chloramines, chlorine dioxide, bleach, or emerging technologies such as photocatalytic anatase titanium dioxide ( $\text{TiO}_2$ ), for example, TioxyClean™, etc.
- *FOG, solvent, and hydrocarbon removal.* Organics for example, benzene, toluene, xylene – BTX) can be removed using coalescers such as American

**Photo 9** (a) Filters removing oil and organics from water, (b) twin ion-exchange water softeners with salt tank and chemical feed station, (c) demineralization and RO plant, (d) deaerator.

Petroleum Institute (API) separators, corrugated plate interceptors (CPI), or dissolved air flotation (DAF) units.<sup>17</sup> A secondary filtration system such as bentonite, organoclay, or similar full-flow media filter (e.g., Biomin™) may also be required.<sup>18</sup> Also advanced filtration/absorption processes may be used, although careful designs are needed as the rule of thumb is often that 50% of costs are incurred for the first 99% of contaminant removal, with the other 50% being spent on the last 1%.<sup>19</sup>

- *Hardness and/or silica removal.* This can be achieved through hot/cold lime and lime-soda softening or ion-exchange. An ion-exchange water softener is a synthetic zeolite softener containing an ion-exchange water softener resin. This ion-exchange resin adsorbs calcium and magnesium ions from the water passing over the resin bed. The resin at the same time releases sodium, hence the term 'ion exchange.' It is often not economical to use softeners for open cooling tower condenser water, evaporative condensers, chilled water and closed loops, hot water

generators, and surface spray units, as these systems operate at pH values close to the neutral point, where the hardness can be kept in solution with the aid of antiscalents and pH control types of chemical treatments. However, chemical treatments will be required even if most of the hardness is removed.

Waters with a hardness of more than 300 or 400 mg l<sup>-1</sup> require at least partial softening so that they can be used for cooling tower makeup water. With steam boilers, however, removal of hardness from the makeup water is nearly always required to remove the hardness, and prevent risks of excessive scale or sludge deposits on heat-transfer surfaces. With steam boilers, the determining factors are both the hardness and the amount of makeup water used. In low-pressure heating applications where steam is used for heating only and possibly small amounts of humidification requiring less than 10% of the steam generated, the boiler feedwater will consist of 90% or more of return steam condensate. In instances such as this, the makeup water will not require external hardness removal as the small amount of hardness entering the system can be controlled with internal treatment.

- *Heavy metal removal.* Metals such as iron, lead, nickel, chromium can be removed by coagulation and alkaline precipitation, or by use of carbamates. Also used is absorption on waste treatment residues (WTR – a lime-based product) or iron-coated olivine (a magnesium–iron silicate) – usually at a neutral to acid pH.
- *Iron and manganese removal.* Fe and Mn are common contaminants in many water sources and may be removed by use of aeration, coagulants, manganese greensand/permanganate techniques, or BIRM™ filters.
- *Removal of volatile organic compounds (VOCs), organics, ammonia, chlorine, color, turbidity, BOD, and COD.* A wide range of organics and other contaminants may be removed from water by using air scouring, activated carbon filters, bio-reactors, redox chemicals, or traditional activated sludge methods.
- *Wide-spectrum contaminant removal.* In addition to the above processes, various membrane techniques (e.g., microfiltration, EDI, RO) may be employed, either as stand-alone processes combined with deionization (DI) or as part of more complex pretreatment arrangements to remove oils, organics, etc.<sup>19</sup>
- *Mechanical removal of oxygen.* In many boiler plant installations, it is economical, necessary, or simply

good practice to remove oxygen in the boiler feedwater by use of feedwater heaters or mechanical deaeration (prior to use of a chemical oxygen scavenger for final removal of corrosive gases), in order to prevent serious corrosion and pitting of steam boiler feedwater lines and boiler tubes. Whenever a steam boiler system is open to the atmosphere through vented condensate receivers, feedwater tanks, etc., the air absorbed will result in high quantities of dissolved oxygen. This increases in direct proportion to the amount of makeup water used because the cold raw makeup water is high in dissolved oxygen. High levels of cold makeup water will not only increase the dissolved oxygen content, but also will lower the temperature of the feedwater in the return condensate tank, enabling more oxygen from the atmosphere to be dissolved in the feedwater. This happens because the solubility of oxygen in water is inversely proportional to temperature.

Modification of the feedwater for oxygen removal is best carried out by using a deaerator. The mechanical pressure deaerator is a complex device that utilizes steam injection to scrub the incoming makeup water and condensate for removal of the dissolved corrosive gases, oxygen and carbon dioxide. In the deaerator, water is sprayed over inert packing or trickled through baffles or trays to break up the water and provide for intimate mixing of the feedwater with the incoming steam. The steam is injected counter to the flow of the incoming water, which drives the gases, oxygen and carbon dioxide upward out the vent. The vent releases only noncondensable gases and steam losses are at a minimum. Some deaerators can produce feedwater with dissolved oxygen content as low as 0.005 cm<sup>3</sup> l<sup>-1</sup> (0.0072 ppm).<sup>20,21</sup>

#### 4.27.11 Modifying Waterside Environments by Appropriate Metal and Alloy Materials Selection

Corrosion protection of metal surfaces contacting water is an ongoing management, maintenance, and control problem, as has been discussed elsewhere. However, better selection of appropriate materials at the design stage can help minimize initial corrosion risks; therefore, consideration of the galvanic series at the material selection stage is a useful exercise. Also, metals may only be vulnerable

under very specific operating conditions; therefore, a simple galvanic series guide may not, by itself, be satisfactory and further investigation may be required. Simple things like flow rate, high cycles of concentration, or high chlorides may initiate corrosion problems.

**Table 4** provides a limited corrosion vulnerability summary.

An example of the need for appropriate materials selection is when employing high chloride waters in cooling systems containing stainless steels, as it is well known that high chlorides will increase the risk of stress corrosion cracking in austenitic stainless steels (e.g., types 304/304L/316/316L) and will tend to increase general corrosion and attack in localized areas, often causing pitting type corrosion. Specifications for the upper limits of tolerance to chloride ions, where the cooling system contains a high percentage of 304L stainless steel (SS) or there is concern over vulnerability of stainless steel components, will typically designate  $200 \text{ mg l}^{-1} \text{ Cl}^{-}$ . Nevertheless, high natural chlorides can often be tolerated in recirculating water at levels of

$600\text{--}800 \text{ mg l}^{-1}$ , and estuarine water users can find seasonal fluctuations raise the chloride in their systems to perhaps  $800\text{--}1200 \text{ mg l}^{-1} \text{ Cl}^{-}$ . This latter level is probably the maximum that can be tolerated under normal circumstances for 304-grade SS and requires good management if serious problems are to be avoided.<sup>11</sup>

The maximum chloride limit for 316-SS grades is generally set by technical organizations at  $1000 \text{ mg l}^{-1}$  but higher concentrations can sometimes be tolerated, and up to  $5000 \text{ mg l}^{-1} \text{ Cl}^{-}$  have been reported in refinery water reuse programs.<sup>17</sup>

At chlorides concentrations of up to  $3600 \text{ mg l}^{-1}$ , a duplex SS is recommended (e.g., 2205-grade) and seawater requires superaustenitic or superduplex SS grades.<sup>27</sup>

Where specific metals and alloys have been selected, part of the ongoing control of corrosion risk is to monitor corrosion rates *in situ* using test pieces, coupons, and various forms of test meters. An example of a corrosion test coupon is shown in **Photo 10**. The corrosion coupon test method has been described by the National Association of Corrosion Engineers (NACE) and is consistent with the ASTM standard 'Corrosivity Testing of Industrial Cooling Water (Coupon Test Method).' The test coupon is placed in the recirculating water system in a test coupon 'rack.' The corrosion test report will include the calculated corrosion rate in mils per year or micrometers per year and other pertinent data such as depth of pits, variations, and types of corrosion deposits.

In cooling systems, the results of corrosion monitoring can be usefully interpreted from **Table 5**.

#### 4.27.12 Understanding Contaminant Saturation Problems as a Precursor to Modification of Waterside Environments by Chemical Inhibitors

In most sources of water, apart from estuarine water and seawater, calcium bicarbonate is usually the most abundant salt found; but it has only limited solubility

**Table 4** Corrosion vulnerability summary

<i>Metal</i>	<i>Type of corrosion risk in water</i>
Steel	Stagnant water tends to induce local attack Fouling induces concentration cell type corrosion High $\text{Cl}^{-}$ and $\text{SO}_4^{2-}$ tend to increase risks of pitting $\text{O}_2$ saturated water may induce general corrosion Fouling and $\text{SO}_4^{2-}$ induce corrosion from sulfate reducers Coupling with noble metal causes galvanic corrosion pH 4.0 induces rapid acid-induced wastage and pitting
Iron	Presence of some $\text{O}_2$ , plus deposits and low flow, stimulate tuberculation Soft water, low pH, $\text{H}_2\text{S}$ can stimulate graphitization
SS	Vulnerable to depassivation from high $\text{Cl}^{-}$ and $\text{SO}_4^{2-}$ Residual or applied stress with $\text{Cl}^{-}$ induces SCC.
Brass	Ammonia produces cracking & wastage. High velocity can induce erosion-corrosion (>6 fps) Uninhibited brass suffers dezincification
Zinc	High alkalinity causes white rust
Al	pH over 9.0 with $\text{OH}^{-}$ causes rapid corrosion

**Photo 10** Corrosion test coupon.

**Table 5** Guide to specifying and quantifying corrosion rates*Interpretation of cooling system corrosion rates*

Description	Rate (mpy)	Comment <sup>a</sup>
Negligible	<2.0	Excellent. Very difficult to achieve.
Mild	2.0–4.0	Good. Acceptable for most situations.
Moderate	4.0–6.0	OK. Probably adequate protection.
High	6.0–8.0	Poor. Doubtful protection.
Severe	>10.0	Very poor. Probably unacceptable protection.

<sup>a</sup>For closed systems, same comments apply if steel mpy is 50% of above rates. For Cu and brasses the same comments apply if mpy is 10% of above rates.

and under conditions where concentration effects take place, as in a cooling system, it will break down to calcium carbonate and form troublesome crystalline scale or sludge deposits. This effect also takes place where heating occurs, as in a boiler, because of an inverse solubility.

Similar effects occur in seawater, where although sodium chloride will be present at levels exceeding 35 000 mg l<sup>-1</sup> (ppm) calcium bicarbonate will be present only at approximately 400–420 mg l<sup>-1</sup>; if the seawater is heated (as in a multistage flash evaporator for the generation of potable water), the calcium bicarbonate will again breakdown to form calcium carbonate scale. Of course, the sodium chloride salt presents another problem, one of corrosion, and it is common to find some form of corrosion associated with most scaling deposits. Scaling and deposition problems often occur in the same water system, and therefore modification of a waterside environment to control one problem must, of necessity, take into consideration the opposite problem at the same time.

Calcium carbonate (CaCO<sub>3</sub>) can form as both aragonite and its polymorph, calcite, which has the same chemistry as aragonite, but a different crystal structure and shape. Aragonite is thermodynamically unstable at standard temperature and pressure, and tends to transform to calcite. Under most heating or concentration-effect conditions in water systems where amorphous or crystalline calcium carbonate scales develop, it is generally considered that calcite is preferentially formed, as it is the most stable form of crystalline calcium carbonate scale. This may simply be a measure of convenience rather than a fact always; however, it allows us to consider the concept of saturation of a

salt or compound in water and the resulting effects of exceeding saturation level concentrations.

A water is said to be saturated with a compound (e.g., calcium carbonate, tricalcium phosphate, amorphous silica,) if it will not precipitate the compound and it will not dissolve any of the solid phase of the compound when left undisturbed, under the same conditions, for an infinite period of time. Water which will not precipitate or dissolve a compound is at equilibrium for the particular compound. Water from which a compound precipitates is supersaturated with respect to that compound. The precipitate is a foulant and may also cause crystalline scaling deposits to be formed. Calcite is the most common foulant. By definition, the amount of a calcium carbonate that can be dissolved in a water and remain in solution for this infinite period of time is described by the solubility product.

$$K_{sp} = (\text{Ca})(\text{CO}_3)$$

where (Ca) is the activity of calcium; (CO<sub>3</sub>) is the carbonate activity;  $K_{sp}$  is the solubility product for calcium carbonate at the temperature under study.

The degree of saturation of any compound (such as calcite) in water is described by the relationship of the ion activity product (IAP = (Ca)(CO<sub>3</sub>)) to the solubility product ( $K_{sp}$ ) for the compound as follows:

- If a water is undersaturated with a compound (IAP <  $K_{sp}$ ), then it will tend to dissolve the compound
- If a water is at equilibrium with a compound (IAP =  $K_{sp}$ ), then it will not tend to dissolve or precipitate the compound
- If a water is supersaturated with a compound (IAP >  $K_{sp}$ ), then it will tend to precipitate the compound.

The saturation index (or degree of supersaturation) describes the relative degree of saturation as a ratio of the ion activity product (IAP) to the solubility product ( $K_{sp}$ ), such that<sup>22,23</sup>:

$$\text{SI} = \frac{\text{IAP}}{K_{sp}}$$

Under typical practical operating conditions, the solubility of calcium carbonate in CO<sub>2</sub>-free water at 15 °C is estimated as only 14 mg l<sup>-1</sup> and so modification of the waterside environment is required to prevent calcite scaling.<sup>11</sup> This usually requires the application of an antiscalent chemical. There are a

**Anodic reactions:****Cathodic reactions:**

**Figure 3** Corrosion reactions forming rust blisters over pit.

wide range of water treatment chemistries (polyacrylates, phosphonates, polymaleates, etc.) available in the market today and antiscaling inhibitor formulation blends based on one or more of these chemistries will typically be able to control the risk of fouling in strongly scaling waters where the calcite SI exceeds 100; and often 150.

For any water under specified operating conditions, the IAP and SI for a range of contaminants (and thus the risk of fouling) can be calculated using industry-available software programs.<sup>24</sup> These modern programs overcome the operational interpretation problems (such as a failure to take into account common ion effects) of early, noncomputerized indices, for example, the Langelier saturation index (LSI).

#### 4.27.13 LSI and Related Indices as an Aid to Modification of Waterside Environments

In condenser water systems using recirculating cooling tower water or once-through cooling water, the water temperature is much lower than that in steam boiler or hot-water systems. At these lower temperatures most of the scale-forming minerals will remain in solution, but the tendency will be to deposit calcium carbonate (calcite) on the heat-transfer surfaces where there is a slight rise in temperature. Modification of a water to reduce the risk of fouling, scaling, and/or corrosion requires that certain analytical factors are considered. The primary factors that affect this tendency are the following:

- alkalinity;
- calcium hardness;
- pH;
- total dissolved solids; and
- temperature.

The higher the alkalinity of a particular water, the higher the bicarbonate and/or carbonate content. As these minerals approach saturation, they tend to come out of solution and precipitate as a calcite foulant or scaling deposit. Likewise, a higher concentration of hardness will increase the tendency of calcium and magnesium salts to come out of solution. The pH value reflects the ratio of carbonate to bicarbonate alkalinity.

The higher the pH value, the greater the carbonate content of the water. As calcium carbonate and magnesium carbonate are less soluble than the bicarbonate, they will tend to precipitate as the pH value and carbonate content increase. Also affecting this tendency are the TDSs and temperature. The higher the solids content the greater the tendency to precipitate the least soluble of these solids. The higher the temperature, the greater the tendency to precipitate the calcium and magnesium salts because of their property of inverse solubility.

- **Langelier saturation index (LSI).** This, developed in 1936, is a calcium carbonate saturation index that is very useful in determining the scaling or corrosive tendencies of a water sample under investigation. It is based on the assumption that any given water with a scaling tendency will tend to deposit a corrosion-inhibiting film of calcium carbonate and hence will be less corrosive. By inference, water with a nonscaling tendency will tend to dissolve protective films and be more corrosive. This is not entirely accurate as other factors are involved in corrosion, but, although a relatively simple tool, it provides a valuable index in determining the tendency of water to directly influence scaling or corrosive actions.

The LSI is on the basis of the pH of saturation of calcium carbonate. The pH of saturation (or 'saturation pH,'  $\text{pH}_s$ ) of calcium carbonate (calcite) is the theoretical pH value of any particular water if that water is saturated with calcium carbonate, and is given by the formula below:

$$\text{pH}_s = (9.3 + A + B) - (C + D)$$

where  $A = (\log_{10} [\text{TDS}] - 1)/10$ ;  $B = -13.12 \times \log_{10} (^\circ\text{C} + 273) + 34.55$ ;  $C = \log_{10} [\text{Ca}^{2+} \text{ as } \text{CaCO}_3] - 0.4$ ;  $D = \log_{10} [\text{alkalinity as } \text{CaCO}_3]$

or

$$\text{pH}_s = 12.3 - (\log_{10} \text{Ca} + \log_{10} \text{TA} + 0.025 \text{Temp} - 0.011 \text{TDS}^{\frac{1}{2}})$$

**Table 6** Makeup water requirements decrease with increasing COC

Makeup water volumes based on an evaporation rate of 5000 m <sup>3</sup> day <sup>-1</sup>		
Bleed rate assumes no windage loss		
COC	Bleed (m <sup>3</sup> day)	Makeup (m <sup>3</sup> day <sup>-1</sup> )
2×	5 000	10 000
3×	2 500	7 500
4×	1 666	6 666
5×	1 250	6 250
6×	1 000	6 000
7×	833	5 833
8×	714	5 714
9×	625	5 625
10×	555	5 555

where Ca = calcium Hardness as ppm CaCO<sub>3</sub>; TA = total alkalinity as ppm CaCO<sub>3</sub>; Temp = Temperature as °C; TDS = total dissolved solids ppm.

To determine the Langelier index, the actual pH of the water must be measured, and the pH of saturation of calcium carbonate is calculated from a measure of the total alkalinity, hardness, TDSs, and temperature. Once the pH of saturation of calcium carbonate has been calculated, the LSI can be determined from the formula.

$$LSI = pH - pH_s$$

A positive index indicates scaling tendencies; a negative one (by inference), corrosion tendencies as shown below:

- If LSI is negative: No potential to scale, the water will dissolve CaCO<sub>3</sub>. An LSI of -2.5 is extremely corrosive
- If LSI is positive: Scale can form and CaCO<sub>3</sub> precipitation may occur. An LSI of +2.5 is extremely scale-forming
- If LSI is close to zero: Some risk of either/both scale/corrosion. Water quality, changes in temperature, or evaporation could change the index.

An LSI of 2.5 is approximately equivalent to a calcite saturation index (CSI) of 150

- *Ryznar index (Ryznar stability index, SI, RSI)*. This is another useful tool for determining the scaling tendencies of water. This index is also on the basis of the pH of saturation of calcium carbonate and was intended to serve as a more accurate index of the extent of scaling or corrosion in addition to

the tendency. This index was derived from the LSI by observation of actual cooling water conditions and is calculated as follows:

$$RSI = 2(pH_s) - pH$$

where pH<sub>s</sub> = pH of saturation of calcium carbonate, pH = actual measured pH of the water, RSI <6 the scale tendency increases as the index decreases, RSI >7 the calcium carbonate formation probably does not lead to a protective corrosion inhibitor film, RSI >8 mild steel corrosion becomes an increasing problem.

- *Puckorius scaling index (PSI)*. LSI and RSI are limited in their absolute relevance as they do not account for two other critical parameters: the buffering capacity of the water, and the maximum quantity of precipitate that can form in bringing water to equilibrium. Puckorius attempts to quantify the relationship between saturation state and scale formation by incorporating into the index an estimate of buffering capacity of the water. However, it is debatable whether, in a practical situation, this additional estimate is of real value, as common ions effects still bring other factors into the overall situation. Common Ion effects are taken into account in IAP modeling, such as the various FrenchCreek® software programs.<sup>24</sup>

Water high in calcium, but with low alkalinity and buffering capacity can have a high calcite saturation level. The high calcium level increases the ion activity product and a plot of ion activity product against precipitate for the water would show a rapid decrease in pH as calcium carbonate is precipitated because of the low buffering capacity. Even small decreases in carbonate concentration in the water would significantly decrease the ion activity product because of the small quantity present prior to the initiation of precipitation. This water might have a high tendency to form scales because of the driving force but any scale formed would be a small quantity and practically unobservable. Thus, the water has the driving force but not the capacity and ability to maintain pH as precipitate matter forms. PSI is calculated in a manner similar to the RSI; however, Puckorius uses equilibrium pH rather than the actual system pH to account for the buffering effects:

$$PSI = 2(pH_{eq}) - pH_s$$

where pH<sub>s</sub> is the pH at saturation of calcite or calcium carbonate, pH<sub>eq</sub> = 1.465 × log<sub>10</sub>[Alkalinity]

+ 4.54,  $[\text{Alkalinity}] = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{OH}^-]$ .

Interpretation of PSI is the same as for RSI.

- *Larson–Skold index (L-SI)*. The L-SI indicates the corrosivity of water towards mild steel and is based on the evaluation of actual corrosion rates and the type of attack on mild steel lines transporting Great Lakes waters. The index is the ratio of equivalents per million (epm) of sulfate ( $\text{SO}_4^{2-}$ ) and chloride ( $\text{Cl}^-$ ) to the epm of alkalinity in the form bicarbonate plus carbonate<sup>26</sup>:

$$\text{L-SI} = (\text{epmCl}^- + \text{epmSO}_4^{2-}) / (\text{epmHCO}_3^- + \text{epmCO}_3^{2-})$$

Extrapolation of observed corrosion results to other waters, such as low or very high alkalinity waters, goes beyond the range of the original data. The index has proven a useful tool in predicting the aggressiveness of once-through cooling waters. The L-SI may be interpreted in the following way:

- L-SI = <0.8: Chlorides and sulfate probably will not interfere with natural film formation;
- L-SI = 0.8–1.2: Chlorides and sulfates may interfere with natural film formation and higher corrosion rates might be anticipated;
- L-SI ≥ 1.2 A tendency towards higher localized corrosion rates should be expected as the index increases.

#### 4.27.14 Use of Contaminant Cycling Effects in Modifying Waterside Environments

The previous section discussed the problem of exceeding calcite saturation limits in water and the very real risks of producing scaling deposits. Calcite scaling risks tend to increase in waters with higher alkalinities, but conversely, the propensity for general corrosion tends to fall, because of the shielding effect of calcium carbonate foulant at the heat exchange surface. This reduced corrosion risk might be considered a benefit, and thus, it is common in both boiler waters and recirculating cooling waters to increase alkalinity levels as an aid to reducing corrosion.

In both steam raising boilers and cooling systems, evaporation of water takes place with makeup water replacing that lost by evaporation and, as the

makeup waters will inevitably contain dissolved gases and mineral contaminants, concentration effects take place which can lead to an increase in contaminants, including alkaline salts. Of particular interest is that the concentration of (alkaline) calcium bicarbonate will increase, and where breakdown of calcium bicarbonate occurs there is a loss of (acidic) carbon dioxide leading to an increase in alkaline (protective) carbonates.

Thus increasing cycles of concentration can be a simple method of mitigating risks of corrosion. In any water system where evaporation occurs there are always constraints that limit the degree of concentration that can take place, but this is usually well beyond the saturation limits for most scaling contaminants. Thus, operational limits are placed on the water system by periodically blowing down (bleeding off) some of the ‘concentrated’ water and replacing it with fresh makeup water. The overall effect is that for any specific water system, the cycles of concentration (COC), that is, the ratio of concentration of TDS in recirculating water to that of the make-up water, are maintained at a prescribed limit, appropriate for the water system in question. This limit may be from, say, 3–10 cycles for cooling systems, and from 10 to 100 cycles for steam raising boilers.

There is an additional benefit of maintaining an appropriately high COC in a water system, and that is that losses of water because of blowdown (bleed) are controlled and generally minimized, leading to an increase in operational efficiency and a savings in both water and chemical inhibitor costs. It should be noted that evaporation rates are not affected by COC. [Table 7](#) shows the potential for water savings with increase in COC.

Typically, when calculating actual, theoretical, and practical COC in cooling system waters, because of the difficulties of testing for TDS in water, testing for chloride is carried out. Chlorides are very soluble and are not otherwise easily removed from the water. We know that COC relates to the increase in TDS over time in the recirculating water, as evaporation (E) of pure water takes place from the tower (providing the cooling effect) and is replaced by makeup water (MU) containing additional TDS. The record of past COC as well as the potential for improving future operating COC is often a vital key to technically improving water treatment management (adding value).

For any cooling system, there is a limit to the maximum COC that can be obtained. The limit is essentially on the basis of the loss of TDS-containing

**Table 7** Contaminant limits in cooling waters

<i>TAB result</i>	<i>Evaluation</i>
0 to 10 <sup>2</sup> colonies per ml	Excellent control
10 <sup>2</sup> to 10 <sup>3</sup> colonies per ml	Warning, but no serious fouling risk
10 <sup>4</sup> to 10 <sup>5</sup> colonies per ml	10 <sup>4</sup> is the maximum permitted for healthcare 10 <sup>5</sup> is a typical maximum for commerce/industry
10 <sup>5</sup> to 10 <sup>6</sup> colonies per ml	Unacceptable. Fouling anticipated. Also, a possible health risk
>10 <sup>6</sup> colonies per ml	Serious risk of fouling and pathogens

water, that is, windage or drift (D), deliberate purge or bleed (B), and leaks. If all leaks and bleed can be halted, then:

$$\text{COC}_{\max} = \frac{E + D}{D}$$

Typically,  $E = 1\%$  of water circulation rate (CR) per  $10^\circ\text{F } \Delta T$ .

where  $\Delta T$  = temperature drop over tower,  $D$  is usually in the range 0.01–0.3% of CR for mechanical draft towers.

Also, considering bleed (B):

$$B = (E/\text{COC} - 1) - D$$

#### 4.27.15 Modification of Waterside Environments by Chemical Inhibitors

In general, although a very wide range of chemical inhibitors is commonly available and employed in all types of water systems, the specific selection is based on the needs of the water system under consideration, and such needs may include, for example, green chemistry protocols, food industry requirements, or discharge regulations.

The selection of chemical inhibitors forms part of a water treatment program that is usually water system specific and generally thought of as an ongoing maintenance ‘polishing’ protocol. The inhibitor program is typically designed to also operate in conjunction with water treatment equipment, such as filters, softeners, or deaerators.

Modification of the waterside environment by chemical inhibitors will result in cleaner heat-exchange surfaces, relative freedom from corrosion and other

problems, improved operational efficiencies, reduced cleaning and other maintenance issues, and increased asset lifespan.

#### 4.27.16 Modification of Steam Boiler Waterside Environments by Chemical Inhibitors

The chemicals, equipment, and methods for inhibitor chemical addition, testing, and control required to optimize firetube (FT), watertube (WT) and other types of steam boiler system operations, to reduce the risks of corrosion, scaling, and fouling to accepted minimums must be tailored, not only to each system, but also to each geographic location, as the water quality and contaminant level will vary by location, and also by season. Implementation and optimization of chemical inhibitor programs need to be administered by qualified water technologists – usually those with an engineering or chemistry background.

The chemical inhibitors are usually referred to as ‘internal treatments,’ as opposed to ‘external treatments,’ by which is meant pretreatment equipment.

Modification of steam boiler water systems by chemical inhibitor programs is required to prevent the problems of corrosion, pitting, scale deposits, and erratic boiler operation because of priming, foaming, and carryover. To prevent these problems, correct blowdown and treatment must be applied. HVAC and space heating boilers also require similar modification, although operational conditions may not need to be so tightly controlled. Control over problems such as the supersaturation of dissolved solids, short and long-term overheating, and boiler priming (surging) rely at least as much on good operation. A summary of the most common problems and the chemistries used to modify the waterside environment follows.

- *Blowdown control.* Blowdown of a boiler is the spontaneous removal of some concentrated boiler water from the boiler under pressure. The recommended maximum concentrations of the impurities, which must be properly controlled, are generally specified by codes, insurance companies, or by industry standards or consensus (e.g., ASME Consensus). Actual operating experience will determine the true operational limits for any specific boiler operation.

The maximum allowable cycles of concentration can be maintained by blowing down the boiler water,

in order to remove accumulated boiler water solids. The amount of solids present in the concentrated boiler blowdown water is equal to the amount of solids in the makeup water multiplied by the cycles of concentration. This can be expressed mathematically as

$$\text{Solids leaving} = BCX$$

where  $B$  is the blowdown, gal (l),  $C$  is the cycles of concentration,  $X$  is the total solids concentration of makeup water,  $\text{mg l}^{-1}$  (ppm).

The amount of solids entering the boiler with the makeup is expressed as

$$\text{Solids entering} = MX$$

where  $M$  is makeup water (l, gal).

As blowdown is designed to maintain a specific level of cycles of concentration, the specified level can be kept consistent only if the amount of solids leaving the boiler is equal to the amount of solids entering the boiler. This is expressed as:

$$BCX(\text{solids leaving}) = MX(\text{solids entering})$$

Solving this equation for blowdown  $B$ , we obtain:

$$B = \frac{M}{C}$$

This formula is used to determine a blowdown rate with respect to the makeup rate. In percent, it can be expressed as:

$$\% \text{Blowdown} = \frac{100}{C}$$

- *Control of priming, foaming, and carryover.* Priming of boiler water is the bumping and bouncing of the water level of the boiler during operation. Foaming, however, is a less violent activity and consists of the formation of small bubbles in the surface of the boiling water. Carryover essentially is the contamination of the steam with boiler water and is a result of priming and foaming. However, it can be a more subtle entrapment of boiler water with the steam, causing steam contamination without the evidence of priming and/or foaming. Most frequently, the causes of priming, foaming, and carryover are a result of contamination of the boiler water with oil or other foreign substances. Other causes are excessive solid accumulation because of the lack of blowdown, high alkalinity, over-treatment, and mechanical malfunction.

Modification of the boiler water to reduce the problems of priming, foaming, and carryover will require adequate blowdown and certain adjunct antifoam inhibitor treatments – generally polyethoxylates.<sup>21</sup>

- *Corrosion control.* Control over boiler section system corrosion typically requires a combined approach that includes (following mechanical deaeration), oxygen scavenging, maintenance of passivated films, and pH and alkalinity control. Primary inhibitor chemistries encompass oxygen scavengers that include inorganics such as sodium sulfite and organics such as hydrazine. Sometimes, certain additional conjunctive inhibitor treatments are required, such as sodium nitrate for protection against embrittlement. Also, anodic corrosion inhibitor programs, which employ nitrite, silicate or molybdate chemistries, may be specified in light-duty multifunctional programs for HW heating and lower-pressure steam boiler systems. Additionally, tannin programs, on the basis of blends of certain natural (e.g., quebracho tannin) or synthetic tannins are used as corrosion inhibitors, as they provide a combination of oxygen scavenging, passivating and sludge conditioning functions.

Sodium sulfite is widely employed, and approximately 8 ppm is needed for every 1 ppm of oxygen. As a fairly high sulfite reserve is required (typically 20–50 ppm or more), additional sulfite must be added and so the general rule is 10 ppm of sodium sulfite per 1 ppm oxygen. The maintenance of a slight excess of the oxygen scavenger in the water provides assurance that there is no dissolved oxygen present. Complete water treatment formulations containing sodium sulfite for this purpose will also include a catalyst, ensuring that the reaction between the dissolved oxygen and the oxygen scavenger is instantaneous, even in cold water.

Hydrazine is not widely used as an oxygen scavenger because of its toxicity. Other oxygen scavengers currently used as a replacement for hydrazine include diethylhydroxylamine (DEHA), sodium erythorbate, carbonylhydrazide (CHZ), methylethylketoxime (MEKO), and hydroquinone (HQ). Typical reserves for these materials are very low, perhaps only 0.1–0.2 ppm.

Control over corrosion in the boiler section may also require the use of alkalinity boosters, based on alkali metal hydroxides. Feedwater pH is generally in the range 8.0–9.3. Boiler water pH will vary

depending upon design and pressure rating. For lower pressures the pH will be 10.5–11.5 or 12. For higher pressures, the pH may only be 9.0–10.0.

Control over corrosion in steam and condensate line sections will need to manage the ingress of oxygen and the formation of carbonic acid, and perhaps deal with the corrosive effects of ammonia on copper – which may have been specified as a pH adjuster and steel corrosion modifier. Condensate treatments include neutralizing amines such as morpholine and filming amines such as octadecylamine (ODA), as well as the highly basic ammonia.

- *Scale and deposit control.* This requires control over primarily hardness salts and other scale forming minerals. Usually a water softener will be specified to soften all incoming makeup water, used as boiler feed. Internal inhibitors include coagulation and precipitation chemistries, chelants, polymers, and blends of all these types of chemicals.

Coagulation and precipitation programs are widely used and employ various types of phosphates as a precipitant to provide control over the unwelcome deposition of hardness scales. Carbonates and polysilicates were once commonly used. Chemistries based on neutral and alkaline phosphates are now the primary precipitation programs. Where coagulation and precipitation programs are employed, specific polymeric dispersants are also required. In the presence of excess alkalinity, phosphate is precipitated as calcium hydroxy-phosphate or hydroxyapatite [ $\text{Ca}_3(\text{PO}_4)_2 \cdot \text{Ca}(\text{OH})_2$ ]. Magnesium with hydroxide alkalinity present in the boiler water will form the hydroxide, precipitating as brucite ( $\text{Mg}(\text{OH})_2$ ). In these forms, the particles are more easily dispersed and held in suspension. It is vital to have adequate alkalinity. The basic coagulation and precipitation program includes a phosphate polymer combination used to maintain a sodium phosphate concentration in the boiler water at 20–60  $\text{mg l}^{-1}$ , ensuring that all the calcium has precipitated as phosphate.

Chelant programs, based on the use of ethylenediaminetetraacetic acid (EDTA) and nitrilotriacetic acid (NTA) chemistries, are commonly prescribed for both FT and WT boilers either as replacements for, or used in combination with, phosphate precipitation programs. They act as solubilizers, not precipitants. Chelants should not be used in excess of 2–3  $\text{mg l}^{-1}$  free chelate

because corrosion of iron can be accelerated in the boiler water. Excellent control over the presence of dissolved oxygen is vital, but chelants can provide a very clean boiler.

- All-polymer/all-organic programs are perhaps the most widely used hardness control products today. Very many specialty polymers are now available and widely used in every type and size of boiler. Typically, multifunctional blends are used as phosphate replacements, and act as dispersants and sludge conditioners. They also provide control over specific problems such as iron transport and silica scaling that can affect many industrial boiler systems. The type of polymers employed includes, polyacrylic acid and polyacrylates (PAA), sulfonated styrene/maleic anhydride (SS/MA), and an iron oxide dispersant, the second one (SS/MA) being an excellent  $\text{Ca}_3(\text{PO}_4)_2$  inhibitor/dispersant where soluble Fe is absent. Also, the copolymer based on acrylic acid and 2-acrylamido-methylpropane sulfonic acid (AA/AMPS or AA/SA) is employed as a  $\text{Ca}_3(\text{PO}_4)_2$  inhibitor/dispersant. Additionally, phosphinocarboxylic acid (PCA) chemistries are used as high temperature suspended-solids dispersants and  $\text{CaSO}_4$  scale inhibitors. These polymers are also polyelectrolytes and distort the scale particle/crystal and its growth, rendering it less adhesive to heat-transfer surfaces and more readily dispersed with a reduced tendency to compact into a dense scale. Some modern polymers also sequester hardness similar to the chelants.

Many permutations of dual- or multifunctional programs exist, on the basis of either chelant or phosphate chemistries, together with polymers and related organics. These types of program are widely employed.

- *Control over specific contaminants and higher pressure boilers.* Very specific polymers are used for control over silica, iron, and copper transport.

Coordinated phosphate programs are employed where there is a need to avoid the formation of hydroxyl alkalinity (free caustic) in higher-pressure WT boilers. They require very careful management and control. Variant programs include congruent control and equilibrium phosphate treatment chemistries.

All-volatile programs (AVPs) are also employed in higher-pressure boilers (generally power boilers) and utilize only volatile chemicals, such as ammonia, amines (such as diethylhydroxylamine, DEHA), and other vapor-phase inhibitors (VPIs).

#### **4.27.17 Modification of Cooling System Waterside Environments by Chemical Inhibitors**

Corrosion and deposits of scale, dirt, mud, organic slime/biofilms, and algae growths are the major problems encountered in open recirculating cooling water systems. There is a loss of water caused by both evaporation and windage drift. The water lost by drift will be of the same quality as the recirculating water; that is, it will contain the same amount of dissolved minerals and impurities. The water lost by evaporation, however, will be essentially pure water, devoid of mineral contaminants.

The evaporation of pure water vapor leaves the dissolved mineral contaminants behind in the recirculating water, and as discussed earlier, the water lost by evaporation is replaced by makeup water, containing dissolved minerals and impurities. As a result, there is an accumulation of minerals that constantly increases in the system as more makeup water is introduced. If the cycles of concentration of dissolved minerals are not controlled, eventually the recirculating water will become so saturated that the most insoluble salts will come out of solution and form a scale on heat-transfer surfaces or within other parts of the system. To avoid this, a risk-benefit condition exists, whereby some bleed off is given but COC is strictly limited.

If COC is raised, there are savings to be made in both water volumes and chemical inhibitors consumed. However, the risk of scaling and fouling increases, which can produce significant cost increase because of cleaning, loss of operational efficiencies, and additional maintenance, so a risk-benefit balance has to be calculated. This will be different for each and every type of cooling system, on the basis of system design acceptable maintenance costs, and water quality.

In open cooling water systems, oxygen cannot be economically removed with scavengers because these systems are constantly aerated and therefore, corrosion inhibitors that are effective in oxygen-containing environments must be employed. Also recirculating cooling water systems contain various types of metals and alloys, and inhibitors and environmental conditions maintained must be compatible with these multimetalllic systems. A particular problem associated with these systems is galvanic corrosion caused by bimetallic couples and white rust.

Treatment of recirculating cooling water must first include control of the pH value for both scale and corrosion control – usually within the range of 7.5–9.5. Lower pH values tend to render the

recirculating water excessively corrosive, while higher pH values will result in both amphoteric metal corrosion (as with zinc, brass, and aluminum) and scale-forming conditions. At this pH, modification of corrosion risk is controlled by corrosion inhibitors added to the recirculating water, which usually form a protective barrier on the metal surface either by chemical reaction with the metal surface or by physical or chemical adsorption on the metal surface. An actively corroding metal can be rendered passive though the use of inhibitors that react in this manner. There are many types and combinations of corrosion inhibitors used for open cooling water systems, on the basis of molybdate, zinc, phosphate, and potentially many dozens of organic-based inhibitor chemistries.

The most troublesome mineral scale is calcium carbonate as it is the least soluble of the salts present in the recirculating water. Alkalinity should also be limited to prevent precipitation of calcium carbonate scale. Alkalinity is present in the form of bicarbonates and carbonates which combine with calcium and magnesium to form calcium carbonate and magnesium carbonate. (Calcium carbonate, being less soluble than magnesium carbonate, will form first).

Alkalinity should be limited not only to prevent precipitation of calcium carbonates, but also to prevent high pH conditions, which may be damaging to some system components such as galvanized steel, brass, or cooling tower lumber. In many larger cooling systems operating with hard water, sulfuric acid is employed to reduce alkalinity by forming calcium sulfate, which is much more soluble than calcium carbonate by a factor of more than 100 times.

Smaller cooling systems operating with hard water may use fully or partially softened water. It is not a good idea to use fully softened water as the risk of corrosion increases significantly. In most modern cooling water program chemistries, calcium, in the presence of phosphonates and polymers, is employed as an anodic corrosion inhibitor.

Limits for common contaminants in recirculating cooling water is provided in [Table 8](#).

Modification of the waterside environment will require control over cooling water chemistry. Notes are provided below.

- If the total hardness rises above 600 ppm, the LSI is likely to be above +2.5 to +2.8 and ion-exchange or lime-soda softening is required, ideally using an 80:20 ratio, soft:hard water blend. Alternatively,

**Table 8** Evaluation of control over bacterial growths

<i>TAB result</i>	<i>Evaluation</i>
0 to $10^2$ colonies per ml	Excellent control
$10^2$ to $10^3$ colonies per ml	Warning, but no serious fouling risk
$10^4$ to $10^5$ colonies per ml	$10^4$ is the maximum permitted for healthcare $10^5$ is a typical maximum for commerce/industry
$10^5$ to $10^6$ colonies per ml	Unacceptable. Fouling anticipated. Also, a possible health risk
$>10^6$ colonies per ml	Serious risk of fouling and pathogens

sulfuric acid and/or a special, stabilized phosphate or alkaline phosphate program must be used. All programs require a good understanding of chemistry and excellent monitoring and control.

- Usually, if the total hardness rises significantly, then the total alkalinity will also rise. If total alkalinity rises above 500 ppm, then the LSI is likely to be above +2.5 to +2.8 and dealkalization is required. (Commonly sulfuric acid is employed; also sulfamic acid for small systems). Alternatively, high stability tolerant, organic threshold/crystal modifier polymers are employed, as adjuncts to the chemical treatment program in place.
- Silica should not be permitted to rise above 120 ppm otherwise irreversible silica scaling will occur. The generally accepted limit is 150 ppm, but this is only in highly alkaline water systems (silica is more soluble in caustic alkaline waters, e.g., boiler water).
- In deep well waters, sulfate often comprises 50% or more of the total calcium hardness (i.e., if, for example, the calcium hardness is  $350 \text{ mg l}^{-1}$  (as  $\text{CaCO}_3$ ) and the total alkalinity is, say,  $200 \text{ mg l}^{-1}$  (as  $\text{CaCO}_3$ ), then the difference of  $150 \text{ mg l}^{-1}$  will most likely be because of calcium sulfate). Sulfate concentration in recirculating cooling water should not exceed 1500 ppm, unless a sulfate-stabilizing polymer is present. Maximum level to avoid irreversible sulfate scaling is 1800 ppm, as  $\text{CaSO}_4$ . Ideally use a sulfate stabilizer over 1200 ppm.

Chemical inhibitor chemistries employed as water-side environmental modifiers include the following:

- *Cathodic and anodic inhibitors.* Cathodic inhibitors, such as zinc, promote insoluble deposits that have an insulating effect and block the flow of electrons, limiting the cathodic reaction and hence anodic dissolution. Anodic inhibitors, such as nitrite, assist

film repair over the metal at anodic sites and hence passivate these areas. When using anodic inhibitors it is vital to maintain correct concentration, as if the anodic sites are not completely blocked, the remaining exposed anodic area will be much smaller than before and preferentially and rapidly corrode, because of higher current densities at the anode sites, causing highly localized pitting attack and rapid perforation of sections.

Molybdate inhibitors depend upon sodium molybdate as a weak oxidizer for ferrous metals, promoting a complex passive oxide film. Molybdates are used in combination with other inhibitors such as zinc, phosphate, phosphonates, and organics for synergistic effect to produce highly effective, synergistic corrosion inhibitor formulations. However, because of cost, the molybdate inhibitor blends are usually used at very low levels in open cooling water systems, typically maintaining less than  $5\text{--}10 \text{ mg l}^{-1}$  as sodium molybdate. In fact, because of the improvement in effectiveness of some novel organic chemistries, molybdenum may be present only at a 'tracer' level, as it is easily and accurately tested at low level and can act as an indicator molecule. Under these circumstances, the typical level in the cooling system is, perhaps, only  $1.0\text{--}1.5 \text{ ppm}$  as Mo. There is a secondary benefit, in that the Mo acts as a synergizer to enable other (organic) inhibitors, such as tolyltriazole (TTA) for copper and hydroxyphosphinocarboxylic acid (HPCA), for iron/steel, to function better.

Zinc, when combined with other inhibitors can provide very effective synergistic chemistries. Formulations might be based on zinc-silicate; zinc-phosphonate, zinc-molybdate, zinc-polyphosphate-organic, or zinc-organic-phosphate combinations. The zinc level in the cooling water is usually held to a maximum of  $2\text{--}5 \text{ mg l}^{-1}$ , depending upon the type of formulation. (The United States Public Health Service Drinking Water Standards limit the zinc of drinking water to  $5.0 \text{ mg l}^{-1}$ ). In some cases, zinc discharged even at this level can be toxic to aquatic life. Some discharge criteria limit the permissible zinc concentrations to  $1.0 \text{ mg l}^{-1}$  zinc, or less. In this case, non-zinc inhibitors should be used.

Phosphate inhibitors are used in neutral to slightly alkaline and moderately alkaline cooling water systems, combined with polymers to form formulated blends that inhibit the formation of phosphate sludge. With the development of very effective phosphate scale inhibitors and stabilizing dispersants (such as the copolymers of acrylic acid

and sulfonic acid polymer, and sulfonated polystyrene and maleic acid) alkaline and stabilized phosphate based inhibitor programs have gained wide acceptance. The orthophosphate levels maintained vary from 5 to 20 mg l<sup>-1</sup>. These inhibitors are most effective at high pH and alkalinity and are usually used at pH 8.0–9.0. The formulations require increased scale control from improved polymer and phosphate blends. The organic azole nonferrous metal inhibitors are also necessary for complete protection. Stabilized phosphate programs in various modifications are probably still the most widely used programs around the world, as they are relatively low cost. Generally, they are used in conjunction with sulfuric acid.

Orthophosphates at much lower levels (perhaps 1.5–3.0 mg l<sup>-1</sup>) may be employed as threshold corrosion inhibitors in potable waters, where they inhibit the pickup of lead into the water, stabilize calcium present, and provide some protection against the corrosion of iron and steel pipes. The phosphates used are either phosphoric acid or sodium hexametaphosphate. Silicates can also be used in potable water systems, where they exhibit similar corrosion-inhibiting effects.

- *Organic Scale Inhibitors, Dispersants and Deposit Control Agents.* Starting with the development of polyacrylates in the 1960s, there is now a plethora of organic scale and corrosion inhibitors available today. Most water treatment formulations will contain several organic inhibitor chemistries blended in precise synergistic ratios to produce the most cost-effective inhibitor programs possible. Depending upon the water treatment company or technologist and the specifics of the cooling system, the total level of 'active' organic inhibitor chemicals present in the recirculating cooling water might be between 7.5 mg l<sup>-1</sup> and 30 or possibly 35 mg l<sup>-1</sup>. This is much less than the level of contaminants and reflects the threshold control abilities of the chemicals. The chemicals provide a combination of effects to control corrosion, scale, and dispersion of minerals and salts. The effects include the following:

- adsorption on the metal surface to control corrosion by film formation;
- direct interference with the corrosion mechanism, so that the inhibitor becomes an integral part of the passivated metal surface;
- chelation of metals, to solubilize them, thus preventing fouling (e.g., by Fe) and scaling (e.g., by Ca);

**Photo 11** (a) Scale crystals modified by an organic inhibitor and (b) scale crystals also modified by an organic inhibitor.

- dispersion of minerals and salts by adsorption onto particulate surfaces, causing them to repel each other because of a like charge; and
- scale inhibition because of modification of the growth of the crystal.

**Photos 11(a) and 11(b)** show calcite crystals modified and distorted by organic inhibitors.

#### **4.27.18 Types of Modern Organic Chemical Inhibitors Employed to Modify Cooling System Waterside Environments Against Risks of Scale, Fouling, and Corrosion Control**

The various organic chemistries commonly employed today include<sup>11,16</sup>:

- *Polyacrylic acid and polyacrylates (PAA)*, 2000–3000 molecular weight (MW). Used for lower-stress CaCO<sub>3</sub>

scale inhibition and general dispersive purpose, or as a secondary support to other chemistries.

- *Polyacrylic acid and polyacrylates (PAA) 4000–5000 MW*. Used for lower-stress general dispersion of suspended solids.
- *Polymethacrylic acid and polymethacrylates (PMAA)*. Used for general and  $\text{CaCO}_3$  scale inhibition; also dispersion of suspended solids and iron (Fe) transport.
- *Polymaleic acid (PMA)*. An excellent homopolymer chemistry for  $\text{CaCO}_3$  and  $\text{CaSO}_4$  scale inhibition under severe service conditions, but with limited dispersive powers.
- *Maleic acid/methyl vinyl ether (MA/MVE)*. Used for  $\text{CaCO}_3$  scale inhibition, with good stability in severe stress conditions and where chlorine is employed.
- *Acrylic acid/hydroxypropyl acrylate (AA/HPA)*. Used as a  $\text{Ca}_3(\text{PO}_4)_2$  inhibitor/dispersant and an iron oxides dispersant.
- *Sulfonated styrene/maleic anhydride (SS/MA)*. Available in a variety of styrene/maleic ratios, and an excellent  $\text{Ca}_3(\text{PO}_4)_2$  inhibitor/dispersant where soluble Fe is absent. Also, an iron oxides dispersant.
- *Acrylic acid/2-acrylamido-methylpropane sulfonic acid (AA/AMPS or AA/SA)*. An excellent copolymer used as a  $\text{Ca}_3(\text{PO}_4)_2$  inhibitor/dispersant and a Zn stabilizer.
- *Acrylic acid/sulfonic acid/substituted acrylamide (AA/SA/NI)*. Used as an iron oxide dispersant. Also, as a  $\text{Ca}_3\text{PO}_4$  and Zn stabilizer/dispersant, in the presence of iron, and under high-stress conditions.
- *Acrylic acid/sulfonic acid/sodium styrene sulfonate (AA/SA/SSS)*. Used for  $\text{Ca}_3(\text{PO}_4)_2$  inhibition/dispersion. Also, for calcium phosphonate control and Fe stabilization.
- *Maleic anhydride/ethyl acrylate/vinyl acrylate (MA/EA/VA)*. A terpolymer, used as a  $\text{CaCO}_3$  scale inhibitor and a thermally stable, general dispersant.
- *Aminotri(methylenephosphonic acid) (ATMP)*. A phosphonate used as a lower-stress  $\text{CaCO}_3$  scale inhibitor and building block-corrosion inhibitor for general duty.
- *1-Hydroxyethylidene-1, 1, diposphonic acid (HEDP)*. A standard  $\text{CaCO}_3$  scale inhibitor and building block-corrosion inhibitor. It is reasonably  $\text{Cl}_2$  resistant.
- *Phosphono-butane tricarboxylic acid (PBTC)*. A  $\text{CaCO}_3$  scale inhibitor and building block-corrosion inhibitor under high stress conditions.
- *Hydroxyphosphono acetic acid (HPCA)*. A ferrous corrosion inhibitor, especially designed to be incorporated into ‘all organic’ programs.
- *Phosphonocarboxylic (sulfonated) copolymer (POCA)*. A low phosphorus content,  $\text{CaCO}_3$  scale inhibitor and corrosion inhibitor.
- *Phosphinocarboxylic acid (PCA)*. A number of PCA materials have been designed as suspended solids dispersants,  $\text{CaSO}_4$  scale inhibitors operating under high stress conditions, low phosphorus content, chlorine resistant, ferrous corrosion inhibitors, or zinc stabilizer and building block corrosion inhibitors (especially in soft water).
- *Tolyltriazole (TTA) or benzotriazole (BTA)*. Azoles, used as corrosion inhibitors for copper and brasses.

Under higher-stress operating conditions (i.e., high heat-exchanger ‘skin’ temperatures, regular use of oxidizer biocides, low or high flow rates, high dirt loadings, etc.), improved inhibitor formulations, or higher concentration of inhibitors are employed – or both! Because different waters may require different types of inhibitor and the fact that all water systems are dynamic, with variable flow rates, stress-levels, and operating demands, it is necessary to have automatic adjustment of inhibitor concentrations, using feed and control equipment. Chemicals may be supplied in perhaps drums or totes and proportionally fed to a water system by means of a pump, which is actuated by some type of controller ranging from a simple timer to a web-based energy management device.

**Photo 12** shows a supply of chemical corrosion inhibitor being fed to an industrial cooling water system for gas process application.

#### 4.27.19 Modifying Cooling System Waterside Environments to Minimize Risks of Biological Fouling and MIC

Oxidizer and nonoxidizer chemistries are widely employed to control microbiological and algal growths in cooling systems, to prevent fouling and operational efficiency problems, to reduce health risks, and to prevent MIC. The major forms of biological organisms that thrive in cooling tower waters are bacterial slimes, algae, and fungi. The spores and seeds of these organisms are present in the atmosphere attached to particles of dust, dirt, pollen, and other airborne particulates. When washed out of the air at the cooling tower they find a favorable environment to grow and multiply. These growths cause serious problems of corrosion, fouling, and blockage, and accelerate buildup of deposits. Such growths not only interfere with

**Photo 12** Chemical corrosion inhibitor feeding station.

water flow but also reduce heat transfer and increase energy losses.

Biological growths can be controlled by registered pesticides substances variously called microbiocides, slimicides, algaecides, and fungicides. Examples include the following<sup>28</sup>:

- *Sodium hypochlorite (Bleach)*. Oxidizer. Sodium hypochlorite is supplied as a 11–13% available chlorine solution. Handling is not usually a problem, but the significant volumes required usually make bleach suitable for only smaller cooling systems. In water, bleach rapidly hydrolyzes according to the equation below:

Thus when bleach is used, hypochlorous acid is formed but also sodium hydroxide (caustic soda) tends to increase the pH. Therefore, extra vigilance may be needed if bleach is used in galvanized cooling towers. Bleach is usually dispensed two or three times per week by hand-adding a known volume, although the use of a timer-controlled pump, is a preferred

alternative. Bleach can also be used in combination with sodium bromide solution to produce hypobromous acid.

- *Bromine*. Oxidizer. Bromine based biocides have been used as pesticides, disinfectants, algaecides, and slimicides for 40–50 years or more, in agriculture, the pulp and paper industry, once-through turbine condenser cooling, and the chemical industry. In the late 1970s and early 1980s, a major step forward came in cooling water treatment technology with the introduction of programs based on bromine release agents. This was primarily bromo-3-chlorodimethylhydantoin (BCDMH), which is available as granules and in various sizes of tablet (puck) and stick. Most bromine biocides employ chlorine in some form, as an ‘activator’ to produce the primary biocidal species hypobromous acid (HOBr). During the last 20 years, the use of programs based on bromine chemistry has become standard practice. Bromine/chlorine-based biocides have become internationally accepted as mainstream products for all types of cooling water systems, brewery pasteurizers, and many other process applications. Bromine/chlorine biocides are now available in many permutations of composition and form.
- *DBNPA*. Nonoxidizer. 2-2-Dibromo-3-nitrilopropionamide. Organo-bromine group. Effective, general-purpose bactericide but hydrolyzes rapidly above pH 8.0. DBNPA is suitable for bacterial slime cleanup where high levels of organics and biomass are present. It functions in conjunction with chlorine. DBNPA is suitable for once-through cooling systems, because of its fast acting biocidal action (contact time often less than 1 h). DBNPA is not particularly effective against algae. The half-life of DBNPA decreases rapidly with increasing pH and temperature. This is not generally a problem because of the short contact time required, and may be a benefit when required to meet strict discharge regulations.
- *DTEA II*. Nonoxidizer. 2-(Decylthio)ethanamine. Alkylthioamine group. It is designed to operate effectively under a wide range of pH levels (pH 6 to 10 or greater) as a biocidal cleaner. It was also designed as a specific sessile bactericide, biofilm remover, and biofilm growth control agent. DTEA or DTEA II functions by forming reversible chelant complexes with the salts and inorganic ions found in biofilm structures, and it severely weakens the biofilm and reduces its adhesiveness. DTEA or DTEA

It is highly surface active and can be thought of as a 'biocidal soap' to be used for cleanup programs (biofilm debris will quickly be in evidence and foaming may occur), as a biocide component with chlorine (although it is not recommended to be used at the same time as chlorine), and as a maintenance biostat. Application rates are typically 50–100 mg l<sup>-1</sup>. It is consumed as it decays rapidly in heavily fouled systems (typically in 3–4 h); consequently, it is recommended to slowly add the complete dose over a four-hour period.

- **Glutaraldehyde.** Nonoxidizer. Pentane-1,5-dial. Aldehyde group. Glutaraldehyde is a good bactericide, especially with difficult and persistent organisms because of its good penetrating ability. It has limited effectiveness against algae and fungi. The kill mechanism is by cross-linking outer proteins of cell and preventing cell permeability. Glutaraldehyde is a fast-acting biocide (3–4 h, perhaps 4–6 h with difficult slimes), nonionic, nonfoaming, effective over a wide pH range (typically pH 6.5–9.0), and compatible with chlorine. It is also effective against SRBs and biofilms. The half-life tends to be short, depending upon the particular cooling system parameters, but typically 4–12 h. Careful evaluation is needed before application on some larger systems, especially as it may not be particularly cost effective. Glutaraldehyde is readily biodegradable. Typical use concentration is 100–125 mg l<sup>-1</sup> at 45% active material, although heavily slimed cooling systems may need 200–300 mg l<sup>-1</sup> as an initial, cleanup shock dose. It is an effective choice for biological control in air washers. Glutaraldehyde is probably a good biocide where the risk of *Legionella* sp. exists.
- **Isothiazolines.** Nonoxidizer. Alkyl isothiazolin-3-ones. Organosulfur group. Good, wide-spectrum bactericide and algicide that is effective over a wide range of pH. Isothiazolines kill by inhibiting microbial respiration and food transport through the cell wall. It is recognized as an industry standard product for cooling systems but can be expensive. Isothiazolines are supplied to some markets as a 13.9% active concentrated blend (10.1% 5-chloro-2-methyl-4-isothiazolin-3-one and 3.8% 2-methyl-4-isothiazolin-3-one). It is always marketed to the end user, as a 1.5% active (1.11% + 0.39% to 1.15% + 0.35%) in-use blend. Isothiazolines are amber to yellow-green liquids that require very careful handling because of severe skin and eye irritant properties. They are effective against both general aerobic and

**Table 9** Evaluation of control over bacterial growths

<i>TAB result</i>	<i>Evaluation</i>
0 to 10 <sup>2</sup> colonies per ml	Excellent control
10 <sup>2</sup> to 10 <sup>3</sup> colonies per ml	Warning, but no serious fouling risk
10 <sup>4</sup> to 10 <sup>5</sup> colonies per ml	10 <sup>4</sup> is the maximum permitted for healthcare 10 <sup>5</sup> is a typical maximum for commerce/industry
10 <sup>5</sup> to 10 <sup>6</sup> colonies per ml	Unacceptable. Fouling anticipated. Also, a possible health risk
>10 <sup>6</sup> colonies per ml	Serious risk of fouling and pathogens

spore-forming bacteria, over a pH range of 6.5–9.0. Isothiazolines are very effective algicides and fungicides, but only at acid to slightly alkaline pH levels. Contact time is typically 5–6 h. Dose rate is typically 50–120 mg l<sup>-1</sup>, for 1.5% active isothiazoline.

Where waterside environments are modified by the use of biocides, various field and laboratory test methods are available to monitor the recirculating water to obtain a total bacteria count and predetermine the need for further addition or modification of the biocides. Field methods include test strips, dip-slides, and ATP meters. Laboratory methods include plate counts. Tests made periodically during operation of the system will provide a history that will indicate if there is an increase in the bacteria count during any particular season, showing the possible need for a change in biocide program.

The biocide program performance should typically be evaluated on the basis of the total bacteria count (TAB) of microorganism in the recirculating cooling water, as indicated in [Table 9](#).

#### 4.27.20 Conclusion

It can be seen from the foregoing sections that the effective control of corrosion of water systems, by modification of waterside environments is part science, part art, and part experience, requiring a thorough understanding of the collective and often synergistic impact of a wide variety of risk factors that may cause other problems, including scaling and fouling. Additionally, in the primary heat-exchange and heat transfer applications for cooling and heating systems, any proposed environmental modification

program must also take into account the economics, management and operational practicalities.

### Glossary

**Discounted cash flow (DCF)** A method of valuing a project or asset incorporating the time value of money in which all future cash flows are estimated and discounted to their present values using a discount rate that is generally the appropriate cost of capital that may be adjusted to incorporate uncertainties in future cash flows.

**Net present value (NPV)** The total present value of a time series of cash flows.

**Life cycle cost (LCC)** The total cost of ownership over the life of an asset.

**EV** Expected value (currency units)

**FV** Future value (currency units)

***i*** Discount/interest rate (%)

***n*** Number of time periods (normally years)

**PV** Present value (currency units)

### Abbreviations

**CRA** Corrosion resistant alloy

**CRF** Capital recovery factor

**GNP** Gross national product

**PVC** Polyvinyl chloride

**ROI** Return on investment

### Symbols

**A** Annualized cost (currency units)

### 4.31.1 Costs of Corrosion in Individual Organizations

#### 4.31.1.1 Sources of Corrosion Costs

Corrosion is intrinsic to the procurement and operation of physical assets, and costs are inevitably incurred in its avoidance and/or its consequences. Corrosion costs can be disaggregated in several ways. The most obvious way is to differentiate the recognizable 'direct' costs of corrosion control expenditures, including any planned repair or replacement, from 'indirect' or 'consequential' costs that result from unexpected corrosion incidents. Accounting practices dictate that the costs of corrosion are recorded as 'capital' or 'operating' costs.

The direct, capital costs of corrosion arise from:

1. The process for selecting materials and associated protection technologies for the assets, including any materials testing and/or qualification.

2. The additional costs of the chosen materials over the cheaper materials from which the assets could be constructed in the absence of corrosion risks.
3. The provision of corrosion allowances.
4. The application of linings, claddings or coatings.
5. The purchase, installation and commissioning of equipment/systems for the injection of corrosion inhibitors, the application of cathodic or anodic protection, the monitoring or analysis for corrosion control purposes, and the maintenance of operation or containment of hazards in the event of corrosion-induced failures.
6. The prevention of any corrosion that may be anticipated during the procurement/construction phase.

The direct costs of corrosion that arise in service are:

1. Inspection and maintenance/servicing of linings, cladding and coatings, and corrosion control equipment/systems.
2. Consumable costs of chemicals and power used for corrosion control.
3. Planned repair and replacement of equipment/components damaged by corrosion.

Indirect, consequential operating expenditures arise from:

1. Failure analysis and corrosion problem solving processes.
2. Unplanned repair and replacement of equipment/components damaged by corrosion.
3. Revenue losses arising from unavailability of assets at any stage (delayed start up, unscheduled downtime, poor equipment performance) because of unforeseen corrosion damage.
4. Fines, compensation/remediation costs and the costs of lost goodwill and reputation arising from death, injury, or environmental damage because of unforeseen corrosion-induced failure.

Indirect, consequential costs are less obviously quantified but can be very large. Major incidents can result in bankruptcy, withdrawal of the organization's license to operate, and even custodial sentences for accountable individuals.

#### 4.31.1.2 Investment Appraisal

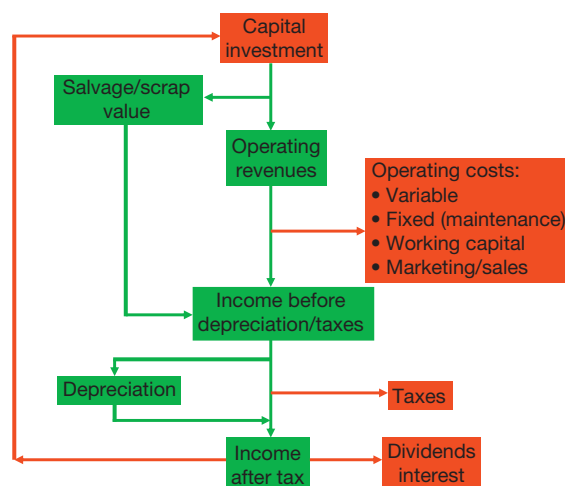

Both commercial and public sector organizations use physical assets and labor to produce and deliver goods and services. Commercial sector organizations

pursue profit whereas public sector organizations usually pursue social/economic benefits arising from the provision of utilities, infrastructures, transportation etc. Simplified, schematic flows of cash arising from investment in commercial organizations are shown in **Figure 1** showing how the cash generated after tax is a source of investment capital for the future.

Any organization, commercial or public sector, must invest in the most profitable or beneficial projects available in order to survive and develop. At any particular time, there is inevitable competition among potential projects for limited capital funds, and organizations need appraisal processes to identify those potential projects that offer the best returns on investment. The simplest process is to favor projects that offer low first cost. However, in the cases of complex assets that are required to operate for many years, more sophisticated appraisal processes that balance the flows of revenues and costs over the whole life cycle, adjusted to allow for factors such as the cost of money and inflation/taxation rates, are required.<sup>1,2</sup>

A key to investment appraisal for the longer term is to recognize and incorporate the time value of money. The value or worth of a unit of money varies with time depending on the prevailing inflation and interest rates. Compounding uses the interest rate to provide a future value or worth of a present sum of money:

$$FV = PV \times (1 + i)^n$$

**Figure 1** Simplified cash flows generated by investment in a commercial organization.

where PV is the present value, FV is the future value,  $i$  is the discount/interest rate (%);  $n$  is the number of time periods (normally years).

The term  $(1 + i)^n$  is the so-called compound factor. Discounting is the reciprocal of the more familiar compounding, in which an interest rate is used to provide a present value or worth of a future sum of money:

$$PV = FV \times \frac{1}{(1 + i)^n}$$

The term  $1/(1 + i)^n$  is the discount factor. Both compound and discount factors are available from tables in standard textbooks for different discount rates and times.<sup>1,2</sup> The effects of interest are incorporated into investment appraisal by the use of discounted cash flow (DCF) procedures in which all capital and operating costs and revenues associated with a particular investment throughout its life, adjusted to incorporate any anticipated effects of inflation, are discounted to their values in a base year. Summation of the discounted positive and negative cash flows at any stage of life produces a net present value (NPV) for the investment.

The patterns of cash flow and the effects of discounting are shown for a hypothetical example of a typical manufacturing investment in Table 1 and Figure 2, based on a major investment in capital assets of 200 currency units in the base year 0. In the two preceding years, -2 and -1, costs of 10 and 50 units, respectively, are incurred in activities such as market research and product and manufacturing

process development. Over the following years 1–10, the assets operate to yield cash flow depending on the balances between sales revenues and the direct and indirect costs of sales and manufacture. In the case depicted in Figure 2, positive cash flows of 80, 90, and 100 units are delivered in years 1, 2, and each of 3–10, respectively, as a result of which net cash flow increases progressively over the operating life of the assets. The effects of discounting at different rates on the present worth of cash flows over time are shown in Table 1 and Figure 2.

Several criteria are available for comparing discounted cash flows for competing potential investments:

1. Money, expressed as the NPV after a given time period. In the case depicted in Table 1, the NPVs after 10 years are 321 and 119 currency units at discount rates of 10 and 20%, respectively, compared with an equivalent net cash flow of 710 currency units.
2. Time, expressed as the 'payback period' at which the cash flow for the project is equal to the original investment. The higher the discount rate, the longer the payback periods. In the case depicted in Figure 2, the undiscounted cash flow pays back at the end of year 2, but at discount rates of 10 and 20% the paybacks are during year 3 and at the end of year 4, respectively.

**Table 1** Net cash flow (NCF) and net present value (NPV) as functions of time for a typical manufacturing investment at discount rates of 10 and 20%

Year	Net cash flow currency units	NPV discount rate	
		10% currency units	20% currency units
-2	-10	-12	-14.5
-1	-60	-67	-75
0	-260	-267	-275
1	-180	-194	-209
2	-90	-119	-147
3	10	-44	-89
4	110	24	-41
5	210	86	-1
6	310	142	33
7	410	193	61
8	510	240	84
9	610	282	103
10	710	321	119

**Figure 2** Net cash flow (NCF) and net present value (NPV) as functions of time for a typical manufacturing investment at discount rates of 10 and 20%.

3. Rate of return on investment (ROI), expressed usually as the average net income for a defined period (usually a year) over the life of the project as a percentage of the total investment. There are various methods for computing ROI. At its simplest, the undiscounted ROI for the case depicted in [Table 1](#) is  $(97/260) \times 100 = 37\%$

The most profitable or beneficial investment is that which yields the highest NPV over the design life of the investment and/or the shortest payback period, and/or the highest ROI.

An alternative basis for comparison is the annualized cost,  $A$ , which is calculated for each of the competing projects or options as follows:

$$A = \frac{PV \times i(1 \pm i)^n}{(1 + i)^n - 1}$$

The term  $i(1 + i)^n / ((1 + i)^n - 1)$  is the capital recovery factor (CRF) that essentially allows the present worth of future expenditures to be converted into an equivalent annual cost that provides for the replacement of equipment to deliver the required operating life and, if appropriate, the decommissioning/scrapping of equipment at the end of the project life. On this basis, the most economic investment is that with the lowest annualized cost. Such evaluations must consider a sensible time period of the number of years for the project assessment to be realistic.

### 4.31.1.3 Identifying the Most Economic Corrosion Control Option

#### 4.31.1.3.1 Life cycle costing

Corrosion control expenditures constitute negative cash flows, although the savings they provide arising from lower maintenance and downtime costs impact positively on NPV, particularly when they replace deficient or even nonexistent corrosion control practices.

In the cases of assets that are at risk of corrosion in service, choices have to be made at the investment stage as to how to mitigate the risks most effectively,

not least the most economic deployment of capital expenditures across corrosion-resistant materials and/or operating expenditures on corrosion control. Essentially, these are alternative investment options that are best evaluated economically using DCF procedures to identify the option with the lowest life cycle cost (LCC). There are well-developed processes for predicting LCCs, including specific guidance on the life cycle costing of corrosion in specific contexts.<sup>3,4</sup> Life cycle costing is usually applied to new assets but is equally applicable to the evaluation of repair, rehabilitation or replacement options for the existing equipment. The use of LCC in both contexts is illustrated in the examples that follow.

#### 4.31.1.3.2 Selecting the most economic material of construction

A decision that faces all car suppliers/owners is the choice of constructional material for the exhaust system. In practice, the three potential materials are unprotected mild steel, aluminized mild steel, and stainless steel that have lives of 2.5, 4, and 10 years at first costs of 60, 80, and 180 currency units, respectively. The simplest approach in identifying the most economic material is to calculate an undiscounted, average yearly cost for each material, as displayed in [Table 2](#). On this basis, stainless steel appears to be the most economic material at an annual cost of 18 currency units per year, but this analysis takes no account of the time value of money.

[Table 2](#) also displays annualized cost,  $A$ , for each of the materials that have been calculated on the basis that money to purchase the exhaust systems is borrowed at an interest rate of 10%, resulting in CRFs of 0.47, 0.32 and 0.16 for mild steel, aluminized steel, and stainless steel respectively. On this basis, aluminized mild steel emerges as the most, and stainless steel the least, economic material.

[Table 3](#) demonstrates an alternative approach to incorporating the time value of money and displays NPV for the three materials on the basis that money to purchase the exhaust systems is borrowed at an

**Table 2** Annualized costs ( $A$ ) for three exhaust system options at a discount rate of 10%

System	First cost currency units	Life years	Undiscounted annual cost currency units	CRF discount rate 10%	$A$ discount rate 10% currency units
Mild steel	60	2.5	24	$\frac{0.1(1.1)^{2.5}}{(1.1)^{2.5}-1} = 0.47$	28.20
Aluminized steel	80	4	20	$\frac{0.1(1.1)^4}{(1.1)^4-1} = 0.32$	25.60
Stainless steel	180	10	18	$\frac{0.1(1.1)^{10}}{(1.1)^{10}-1} = 0.16$	28.80

**Table 3** Net present value (NPV) as a function of time for three exhaust system options at a discount rate of 10%

Year	Cash flow currency units	PV discount rate 10% currency units	NPV discount rate 10% currency units
<i>Mild Steel</i>			
0	60	60.00	60.00
2.5	60	47.28	107.28
5.0	60	37.26	144.54
7.5	60	29.34	173.88
10.0	60	23.10	196.98
12.5	60	18.24	215.22
15.0	60	14.34	229.56
17.5	60	11.32	240.88
<i>Aluminized steel</i>			
0	80	80.00	80.00
4	80	54.64	134.64
8	80	37.36	172.00
12	80	25.52	197.52
16	80	17.44	214.96
<i>Stainless steel</i>			
0	180	180.00	180.00
10	180	69.40	249.40

interest rate of 10% and an operating life for the car of 20 years is required. The outcome is the same as for the annualized cost analysis.

The interest/discount rate has a significant influence as to which material is the most economic. Lower rates favor stainless steel that becomes more economic than mild steel and aluminized steel at interest rates of ~4% and ~9%, respectively. In the 10–20% interest rate range, aluminized steel is the most economic material and only at very high interest rates, 35% and above, does mild steel become the most economic material.

The use of LCC for identifying the most economic materials of construction in a manufacturing context is depicted in **Figure 3** that relates to the hypothetical manufacturing project defined in **Table 1** and **Figure 2**. It is assumed that there are two alternative construction materials for the assets. Stainless steel corrodes at a very low rate and provides a 10-year life at an initial cost of 200 currency units. Mild steel costs only 100 currency units, but corrodes at rates that require extensive repair and refurbishment of assets during years 2–3, 5–6, and 8–9 at a cost of 100 currency units on each occasion. **Figures 3(a) and 3(b)** show discounted cash flows for the two alternative materials of construction at discount rates of 10 and 20%.

At a discount rate of 10%, mild steel pays back marginally earlier than the stainless steel option but, beyond the fifth year, the NPV for the stainless steel

(a)

(b)

**Figure 3** NPVs as functions of time for a typical manufacturing investment constructed in mild and stainless steels at a discount rate of (a) 10% and (b) 20%.

option is increasingly larger. In contrast, at a discount rate of 20%, the mild steel option pays back significantly earlier and, even after 10 years, the NPV advantage offered by the stainless steel option is marginal.

#### 4.31.1.3.3 Deciding among repair, protection, and replacement options

This choice is illustrated by the case of a water main that has experienced a series of leaks because of external corrosion. The options for correction are:

1. ongoing repair of leaks,
2. install cathodic protection to the existing piping system, and
3. replace with a PVC piping system.

The basis for the assessment is that the main is required to operate for a further 40 years at a prevailing 12% interest/discount rate. The assessment is based on a 1-km length of pipe assuming a constant leakage rate of 3 per kilometer per year. Leaks cost an average of 18 currency units to repair.

Cathodic protection using magnesium anodes designed for a 20-year life is estimated to reduce repairs by 95%. The initial installed cost of a cathodic protection system is 180 currency units and the system does not require maintenance.

The installation cost of replacement with a PVC piping system is 1440 currency units per kilometer and a PVC main is expected to have a 40-year maintenance-free life.

Annualized costs for the three options are summarized in [Table 4](#), from which it is clear that installing a cathodic protection system on the existing main is more cost effective than either of the alternative options. Even if the required life of the main was extended from 40 to 90 years, in which case the CRF for replacement would change from 0.121 at 40 years to 0.120 at 90 years, cathodic protection would remain the most economic option.

However, selection of the cathodic protection option assumes that the condition of the main remains sufficiently good for cathodic protection to sustain the ongoing failure rate at 5% of the existing level. If there are doubts about this, the choice reverts to ongoing repair or replacement of the existing main with PVC pipe. At a repair cost of 18 currency units per leak, a leakage rate of 9.7 leaks per kilometer would be required to equalize the annualized cost of 174 currency units for replacement with PVC. Although at face value, this is several times the current leak rate, the assumption that the leak rate will remain constant is probably optimistic. Studies of cumulative leak history curves suggests that leak rates are more likely to increase exponentially with time, in which case replacement is likely to prove a more economic option sooner rather than later.

This illustrates that risks and uncertainties in the various cost inputs to economic evaluations must be recognized and incorporated into decision criteria.

#### 4.31.1.3.4 *Incorporating risks and uncertainties into economic evaluations*

The previous economic evaluations in this chapter have all been deterministic. However, there are inevitable risks and uncertainties in the assumptions and data inputs and these can be allowed for in the evaluations by the use of probabilities. The importance of such analysis has been illustrated<sup>5</sup> for the case of a 10-mile, 6-in. diameter, offshore pipeline, for which the options for mitigating corrosion risks are:

1. carbon steel, protected by corrosion inhibitor addition;
2. carbon steel clad with a corrosion-resistant alloy (CRA).

In a deterministic analysis incorporating all relevant initial and operating costs, the NPV costs based on a discount rate of 10% and a cost escalation rate of 7% are \$12 and \$23 million for the inhibited carbon steel and clad carbon steel options, respectively. On this basis, the inhibited carbon steel option would be installed. However, this analysis does not consider the probability of failure or its economic consequences that are considerable in the case of offshore equipment.

The expected value (EV) method can be used to compare options when there are multiple potential outcomes of a decision. The expected value of a decision is based on Bayesian logic and can be regarded as the 'usual' outcome of many instances of the decision. In the case of the pipeline, it can be used to incorporate the impact of failure as an additional NPV cost on the two base options arising from a single event or multiple events over the life of the pipeline. In the case of the clad pipeline, it is considered that there is a 1% probability of a single or multiple events having an NPV cost of \$25 million. In the case of the inhibited

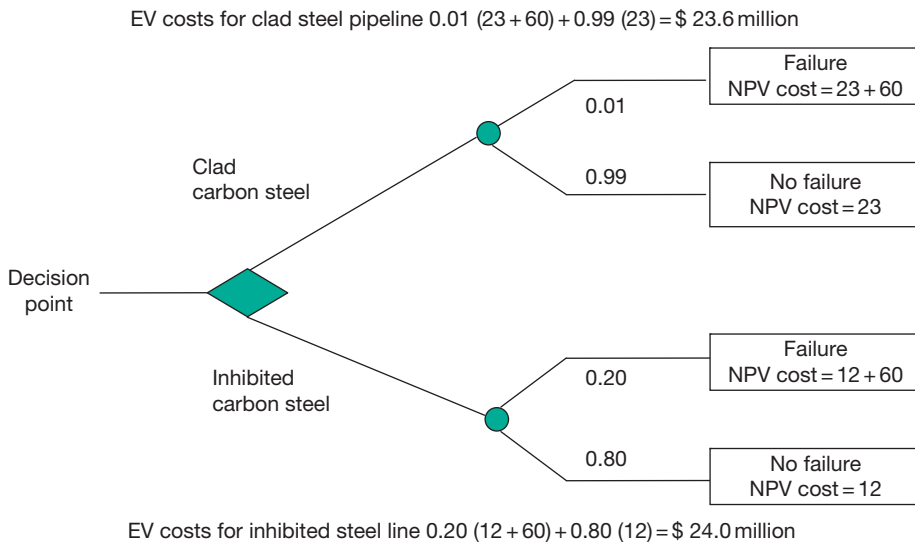

**Table 4** Annualized costs (A) for pipe repair, protection, and replacement options at a discount rate of 12%

Option	First cost currency units	Life years	Annual leakage cost currency units	CRF discount rate 12%	A discount rate 12% currency units
Repair leaks			54	1	54
Cathodic protection	180	20	2.7	0.134	24.1 + 2.7 = 26.8
Replacement PVC pipe	1 440	40		0.121	174

pipeline, the equivalent corrosion risks and consequences are larger and are considered to amount to a 20% probability of an NPV cost of \$75 million. The corresponding EV costs that result for the two options are shown in the decision tree in Figure 4 where it is apparent that the most economic option on this basis is the clad carbon steel pipeline.

In practice, it can be difficult to anticipate the probabilities, costs, and timings of specific possible failures. A more generalized approach to the EV

method is provided by the so-called probability limit curves such as that depicted in Figure 5, based on the equivalence of failure scenarios that have the same NPV cost. In Figure 5, the probability and NPV cost of a clad pipeline failure are set at 1% and \$25 million, respectively and the curve defines the locus of equal EVs for clad and inhibited carbon steel options that separates zones where one or the other option is the economic choice. This provides more flexibility in factoring risk into the decision process.

#### 4.31.1.3.5 General outcomes of LCC approaches

The examples above illustrate some general economic truths relating to the selection of corrosion control options:

1. Relatively low interest rates favor long-term economic planning and the cheapest may well not be the most economic option when LCCs are taken into consideration.
2. Alternatively, when the capital is very expensive, shorter-term considerations tend to dominate and large long-term investments have no merit over small frequently repeated investments. In these circumstances, the cheapest is also likely to be the most economic option.
3. It is essential that the risks and uncertainties attached to the inputs of a decision are understood and incorporated into the process of identifying the most economic option.

As to whether these truths are understood and practiced, a recent UK survey of the costs of corrosion in specific industrial sectors<sup>6–10</sup> revealed an increasing usage of LCC approaches in selecting corrosion control options, but a widespread lack of awareness of the total costs of corrosion in specific organizations. To some extent, this results from accounting practices that make it difficult to disaggregate corrosion costs from standard cost categories such as capital and maintenance costs. However, a detailed awareness of corrosion costs is essential to the development of optimal corrosion control management strategies, particularly, in those organizations where corrosion presents a significant threat to the reliability and availability of operating equipment.

### 4.31.2 Costs of Corrosion in Specific Sectors/Economies

#### 4.31.2.1 Quantifying Corrosion Costs in Sectors/Economies

Over the past ~60 years, there have been numerous studies of the costs of corrosion to specific industrial sectors and/or national economies, including the United Kingdom,<sup>6–11</sup> United States,<sup>12–15</sup> Australia,<sup>16–20</sup> India,<sup>21</sup> Sweden,<sup>22</sup> Finland,<sup>23</sup> West Germany,<sup>24</sup> Japan,<sup>25,26</sup> China,<sup>27</sup> Kuwait,<sup>28</sup> and Canada.<sup>29</sup>

Early studies of corrosion costs tended to concentrate on direct expenditures. For example, Uhlig based his original USA study<sup>12</sup> on quantifying national expenditures on the direct costs of corrosion

across the economy including corrosion-resistant materials, coatings, inhibitors, cathodic protection, and repair and replacement costs. Hoar's later UK study<sup>11</sup> focused on the estimates of recognized industry experts in specific industrial sectors in addition to the surveys of expenditure on corrosion protection measures. The application of the above approaches to the Japanese economy<sup>25</sup> resulted in a higher estimate of total cost using the Hoar rather than the Uhlig approach.

The USA economy has received the most frequent and detailed evaluation and the outputs of the key studies<sup>13–15</sup> are summarized in Figure 6. Following Uhlig's initial 1949 study,<sup>12</sup> NBS Battelle revisited the cost of corrosion to the national economy in 1978 in a much more rigorous study<sup>13,14</sup> that drew on the expertise of professional economists to evaluate sectorwise economic statistics. This approach introduced some top-down evaluation that was missing from Uhlig's earlier study and sought to trace expenditures on corrosion in different sectors of the economy through 'input' purchases of goods and services for corrosion control and their impact on 'outputs' including revenues. This input-output approach estimated a significantly higher cost than the original Uhlig study because it included the consequential costs of corrosion arising from the unavailability of assets and incidents with safety, health and environmental consequences. The 1978 study was updated in 1996 and a completely new study in 2002<sup>15</sup> confirmed a declining trend in total expenditures on corrosion in the 1978–2002 period.

**Figure 6** Total cost of corrosion and potential savings in the USA economy as percentages of GNP in 1949,<sup>12</sup> 1978/1995,<sup>13,14</sup> and 2002.<sup>15</sup>

A later study of the application of the input/output model to the Japanese economy<sup>26,30</sup> confirmed that it produces significantly higher estimates than earlier approaches and concluded that it is likely to estimate costs that are 2–4 times higher than the application of the Uhlig or Hoar approaches.

There is no recognized definitive approach towards estimating the cost of corrosion to industrial sectors and national economies. Some quite detailed models have been proposed<sup>20,31</sup> but all approaches involve degrees of judgment and approximation that reflect uncertainties in the contributions of corrosion to costs in individual organizations or sectors of an economy.

#### 4.31.2.2 Corrosion Costs in Specific Sectors

In recent years, there have been numerous studies of the costs of corrosion in specific industrial sectors. The most recent USA study<sup>15</sup> examined corrosion costs in 26 individual sectors within the broader sectors of utilities, transportation, infrastructure, defense and production or manufacturing. The costs of the top 12 categories, shown in Figure 7 as percentages of the total USA cost of corrosion, provide an overview of the relative sizes of the various sectors

in relation to the expenditures on corrosion control. Drinking water and sewerage systems comprise the most expensive individual sector, and together with electrical utilities and gas distribution they establish utilities as the largest broad sector. Corrosion control in motor vehicles dominates transportation, the second largest broad sector followed by infrastructure, including expenditures on highway bridges, hazardous materials storages, and gas and liquid pipelines. In the grand scheme of things, expenditures on production and manufacturing, including pulp and paper, petroleum refining, chemicals, and oil and gas are relatively small.

As important as the sizes of the various sectors depicted in Figure 7 is the relative efficacies of their expenditures on corrosion control *viz.* to what extent the expenditures represent money well spent as opposed to money wasted. The results of detailed studies of the total costs of corrosion and the potential savings in several sectors in the United Kingdom<sup>6,7,9,10</sup> and the United States<sup>32</sup> are shown in Figure 8 as percentages of turnover. Total expenditures vary from as high as 7% to as low as 1% of turnover in the cases of the USA electric power and UK food and drink manufacturing sectors, respectively. These broad differences are consistent with

**Figure 7** Costs of corrosion in top 12 sectors as percentages of the total cost of corrosion in the USA economy in 2002. Adapted from Koch, G. H.; Brongers, M. P. H.; Thompson, N. G.; Virmani, P.; Payer, J. H. *Corrosion Costs and Preventive Strategies in the USA*, Report FHWA-RD-01-156 to Federal Highways Administration; C. C. Technologies Laboratories, 2001.

the different types of processes and equipments in the different sectors. The USA electric power sector includes nuclear operations with significant corrosion risks to address using very stringent and expensive corrosion risk management procedures. The UK food and drink manufacturing sector is faced with much lower corrosion risks to its predominantly stainless steel equipment and its expenditures are correspondingly lower.

The total expenditures in **Figure 8** are averages in each case based on the ranges of expenditures for individual organizations in the sectors that depend on the type, age and location of their equipment. Thus, in the UK petrochemical/chemical sector, total expenditures ranged from as little as 0.1% of turnover in the case of a small, contract manufacturing company with several glass-/tantalum-lined vessels in excellent condition that had been written off the books, to as high as 8.9% of turnover in the case of a large manufacturer with old assets with major external corrosion problems resulting in significant unscheduled downtime and heavy repair/replacement expenditures.

All the sectors examined made significant and increasing usages of risk-based methodologies in the management of their corrosion problems, including life cycle costing, reliability/availability/maintainability modeling and risk-based inspection. Despite this, all identified scope for further potential savings, ranging from 10% to 22% of the total expenditures in the UK food and drink manufacturing and USA electric power industries, respectively, by applying existing technology and best management practices. In only one sector in the UK study, automotive manufacturing (not shown in **Figure 8**), it was judged that corrosion expenditures were close to the

economic optimum. This sector had been highlighted in Hoar's 1971 study<sup>11</sup> of the UK economy as a particular source of potential savings; since then technology and corrosion management practices have improved in the industry worldwide to the stage where the United States' second highest sector expenditure in **Figure 7** can be classed as money well spent.

#### 4.31.2.3 Corrosion Costs in National Economies

Studies of the costs of corrosion in different countries conclude generally that total corrosion expenditures comprise 3–5% GNP. Intuitively, the level would be expected to vary with the stage of development and mix of industrial sectors in any particular economy and to reduce with time as technology and management practices improve. There is some evidence for this from several studies<sup>12–15</sup> of the large and diverse USA economy over time, summarized in **Figure 6**, where total expenditures have reduced from 4.9 to 3.1% of GNP in the 1978–2002 period. Studies of the UK economy<sup>6–11</sup> widely separated in time suggest a similar trend, driven by improvements in:

1. Advances in corrosion-resistant materials and protection technologies.
2. Improved understanding and dimensioning of corrosion processes including the codification of knowledge in international/national standards, codes of practice and guidance documents in all sectors.
3. Improved corrosion management practices related to materials and protection selection and optimizing the availability and inspection of assets, including new and improved technologies for corrosion monitoring and inspection.

**Figure 8** Total costs of corrosion and potential savings in various sectors of the United Kingdom<sup>6–10</sup> and United States<sup>32</sup> economies as percentages of sector turnover.

Over the same period, although the estimated scope for further potential savings in the USA and UK studies has reduced, it remains at 20–30% of prevailing expenditures as a result of:

1. Legacy issues – problems in ageing structures, designed, fabricated and protected to standards now recognized as inadequate, for example, external corrosion of ‘baby boomer’ process industry equipment, under thermal insulation and fireproofing.
2. Management issues – problems for which there are proven, economic, technical solutions, for example, corrosion in cooling water and steam-raising equipment or in CO<sub>2</sub>/H<sub>2</sub>S-containing produced water and seawater equipment.
3. Technology challenges – problems for which there are no proven economic solutions, for example, materials for chemical/petrochemical equipment that is vulnerable to metal dusting.

All studies recognize that there is scope for further significant reductions in corrosion expenditures by:

1. Promoting awareness and uptake of advanced design and good corrosion management practices.
2. Improving corrosion technology through research, development and implementation, including advanced life prediction and performance assessment methodologies.
3. Improving education and training of staff at all levels in corrosion control and safeguarding university training of future corrosion professionals.

In relation to the availability and deployment of corrosion professionals, the recent UK study<sup>6–10</sup> revealed concerns across all sectors about loss of expertise arising from a progressive decline in numbers employed in user organizations, resulting in a net migration of corrosion expertise to supplier and research/consulting organizations.

A further conclusion of several of the national studies is the potential benefits of changes in taxation policy to categorize operational corrosion control expenditures as capital investments rather than maintenance costs so that they attract tax allowances, thereby promoting front-end approaches towards corrosion control.

Extrapolating the evident trend in **Figure 6** suggests that there is an optimum economic level of expenditure on corrosion for a large, diverse economy within the 2–2.5% GNP range. Although conventionally defined as the ‘cost’ of corrosion, this reinforces a rather negative image for corrosion as

‘engineering’s grim reaper’ in relation to its impact on economic activity. In reality, corrosion control expenditures enable developed economies to sustain high levels of economic activity through the availability and reliability of their infrastructures and wealth-creating physical assets. In the process, they sustain profitable, high-technology businesses that provide employment and pay taxes. These constitute enormous ‘benefits’, as well as ‘costs.’

In relation to the image of corrosion, the corrosion community might learn from the health sector. Human disease is a useful paradigm for corrosion. Developed economies spend 7–14% GNP on the health of their human assets and, although smaller, corrosion expenditure on physical assets, at a current 3–5% GNP, is of the same order of magnitude. Health expenditure is near the top of political agendas in all developed economies with increasing emphasis on predictive/preventative strategies. There is scope to raise the profile of corrosion and protection to achieve commensurate recognition and resources and deliver its full potential benefit to the national economies. This, however, relies on corrosion practitioners and educators being able to apply the basic economic tools of discounting/life cycle costing and to understand their relevance in the context of tactical and strategic decision making.

### 4.30.1 Background to Corrosion Management

#### 4.30.1.1 Introduction

This chapter outlines some general concepts, techniques, methodologies, and interactive processes that together promote successful management of corrosion. A top-down, strategy-based introduction to the subject area is presented together with an introduction to the tactics used to mitigate the effects of corrosion. A holistic overview that accommodates economic aspects, corrosion control methods and corrosion inspection/monitoring practices, which are the subjects of separate chapters in this volume, is provided.

In this section, the background to corrosion management is outlined, including concepts, definitions, legislative drivers, and the need for a risk-based approach. [Section 4.30.2](#) considers basic steps in corrosion management with emphasis on quality processes. In particular, the link between basic corrosion risk assessments (steps involving interactions between materials, environments, and engineering applications) and corrosion mitigation (control options, economics, and monitoring) is considered with the introduction of the requirements of a management system. In [Section 4.30.3](#), the various methods (the tools) for the assessment of corrosion risks and development of corrosion strategies are reviewed. Management systems are addressed in [Section 4.30.4](#) with considerations of further developments in [Section 4.30.5](#). Many of the concepts outlined here will not be found in other chapters of this publication or in most standard corrosion texts and are therefore presented in sufficient detail to avoid the reader having to refer to other engineering/management texts.

#### 4.30.1.2 The Need for Corrosion Management

To manage has been defined as “to succeed in one’s aims (often with inadequate materials etc),”<sup>1</sup> an objective often wryly considered as appropriate by

many corrosion engineers! Corrosion management is a process consisting of a series of steps to convert an input (corrosion risks) into an output (cost effective mitigation of those corrosion risks).

In principle, management of corrosion should be a simple process; the technologies are well established and most organizations understand the need for corrosion mitigation practices that are appropriate to their sector. However, the literature contains numerous reports of catastrophic events that have been caused by corrosion, the root causes of which are frequently poor management control, often identified as human errors:

1. “For many pipework failures, human error is identified as a dominant factor.”<sup>2</sup>
2. “. . . analysis of the major accidents reported in the Community indicates that the majority of them are the result of managerial and/or organizational shortcomings. . . .”<sup>3</sup>
3. “The cause of corrosion failures is human error/poor management control.”<sup>4</sup>

In practice, mistakes occur in the selection of corrosion control options, in application of mitigation technologies and in day-to-day activities needed to ensure that systems are monitored and corrective actions are carried out when necessary. In many instances, failures occur because basic lessons are not learned, particularly in organizations that cannot justify the services of a full time corrosion/materials specialist, and that, therefore, delegate corrosion control/monitoring activities to nonspecialist managers and engineers who may lack the required knowledge/experience. The effective implementation of mitigation practices from the design stage through the construction, commissioning, operation, and maintenance phases requires contributions from various teams of designers, constructors, commissioning staff, operations and maintenance personnel, and contractors and consultants/specialists. For such teams to be effective, they require clear objectives, transparent management systems, and appropriate reporting routes/procedures to ensure that appropriate decisions are made and implemented.

The author acted as a corrosion management expert witness in a case involving a major refinery incident resulting from inadequate control that exemplifies the need for good management practices.<sup>5</sup> An explosion and fire resulted from a rupture of a gas transfer line in a saturate gas plant because of local thinning by erosion–corrosion downstream of a water injection point after 13 years of operation.

The gas contained hydrogen sulfide, and water was periodically injected downstream of the overheads to control fouling of the condensers, a standard refinery practice for hydro-processing units. The heat exchangers had been replaced using corrosion resistant materials a few years previously, but the pipework was original and had been subjected to only one partial inspection. The failure was located on the surfaces downstream of the water injection point, as would be predicted by the injection point drawing in American Petroleum Institute (API) 570.<sup>6</sup> Subsequent discussions of the incident at the National Association of Corrosion Engineers (NACE) refinery work group<sup>7</sup> highlighted the requirement for inspections around any injection point, in intermittent or continuous use, at not more than three yearly intervals. There also appeared to be confusion at the refinery whether the injection point had been taken out of service following such a recommendation. A lack of management control over corrosion assessments/inspection/record keeping and procedures was identified as a major contributing factor to the failure during the subsequent trial. Following the incident, the refinery was shut down for 3 months, and a further 12 months was required to rebuild the gas plant, the company receiving a considerable fine as well.

In reality, the term ‘corrosion management’ is used in various contexts in many publications, but there is no body of knowledge/textbooks that adequately address this subject area, unlike asset management, safety management, and maintenance management. It therefore has different meanings to individuals and groups within the corrosion community. In order to clarify this issue during discussions on industrial short courses, the author developed a general definition in the mid-1990s, based on safety and environmental management definitions that was subsequently adopted in UK documentation for offshore oil and gas processing.<sup>8</sup> The definition also included the concept of a ‘corrosion policy.’ An organization’s policy is normally written by senior personnel, often at board/asset level, and is a statement of intent or an overall objective.

*Corrosion management* is that part of the overall asset management system that is concerned with development, implementation, review, and maintenance of the corrosion policy.

*A corrosion policy* includes establishment of organizational structures with defined responsibilities, reporting routes, practices, procedures, processes, and resources. This requires the demonstration of responsibility and accountability for corrosion performance,

managing risks, decreasing costs, controlling compliance, and motivating personnel.

This definition of corrosion management has also been included by NACE International in their online resource library (management) but without defining the corrosion policy. Most large organizations have until recently not given serious consideration to corrosion policies even though they have as standard practice developed and implemented quality, safety, environmental and maintenance policies. This is in spite of the fact that they often have in place many of the necessary procedures, management structures, activities, and reporting routes required for implementing corrosion policies. It should also be noted that, since the mid-1990s, the UK HSE has also been asking organizations for copies of their corrosion policies but few have even considered such a concept. Such policies written by senior personnel, often at board/asset level, are statements of intent or overall objectives. The lack of a written corrosion policy may mean that the various interdisciplinary and multi-departmental contributions are inadequate to ensure appropriate corrosion mitigation; also the management of corrosion is poorly focused upon at both the senior management level and in the operational/day-to-day activities of an organization.

#### 4.30.1.3 Legislative Drivers

In recent years, there has been an increased emphasis in commercial and public sector organizations on the identification and management of risks to safety, health and the environment (SHE) and to the economic viability that is driven by developments in SHE legislation across the world. A turning point in UK regulatory requirements was the 1990 Cullen Report<sup>9</sup> on the 1988 Piper Alpha offshore platform incident that ensured an increased emphasis on risk assessments and the use of appropriate safety management systems. This cultural shift from a rules-based regulatory system to a principles-based system with emphasis on defined objectives rather than the traditional prescriptive, rules-based practice, is summarized in [Table 1](#).

The principles-based approach places a greater onus on organizations and individuals (the duty holders) to demonstrate a continuously improving safety culture with emphasis on regular assessment of risks, monitoring of performance and a proactive approach. Legislative enforcement, by the UK HSE with Statutory Instruments (SI), is the basis of the

**Table 1** Legislative changes

<i>Older legislation</i>		<i>Principles-based legislation</i>
Detailed rules and regulations	→	Framework rules with guidelines
What must be done		How it must be managed
Prescriptive		Risk-based
Do it anyway		Identify hazards and risks first and prioritize actions accordingly

formal UK regulations that are typically based on European requirements as given in normative European standards (EN) and ISO standards.

The UK changes were first indicated in the 1991 publication of *Successful Health and Safety Management*<sup>10</sup> followed by requirements for the UK offshore oil and gas production in the *Safety Case Regulations*, in 1992<sup>11</sup> the *Design and Construction Regulations*<sup>12</sup> and the *Pipeline Standard*<sup>13</sup> in 1996. The general approach continued in *The Control of Major Accident Hazard Regulations* 1999 (COMAH)<sup>14</sup> for major hazard sites such as refineries and chemical plants and in the *Pressure Systems Safety Regulations* (SI 2000/128).<sup>15</sup>

The overall thrust of these approaches is illustrated as follows:

1. Reg. 8 of SI 1996/913:<sup>12</sup> The duty holder shall ensure that auditable arrangements are in place for maintaining the integrity of the installation, including suitable arrangements for: (1) periodic assessment of its integrity and (2) the carrying out of remedial work in the event of damage or deterioration which may prejudice its integrity.
2. Reg. 13 of SI 1996/825:<sup>13</sup> The operator shall ensure that the pipeline is maintained in an efficient state, in efficient working order and in good repair.
3. Reg. 12 of SI 2000/128:<sup>15</sup> The owner of an installed (pressure) system shall ensure that the system is properly maintained in good repair, so as to prevent danger.

In particular, written schemes of examination are required for pressure vessels and associated pipework.<sup>15</sup> Such documents have to be prepared by a competent person, either a named individual or a corporate inspection body within the organization. The accompanying Approved Code of Practice L122<sup>16</sup> provides further background information and it also notes that, "the contents may be highly toxic or the plant may form part of a major hazard site. These aspects are all subject to separate

legislative requirements and duty holders will need to consider these other aspects (corrosion and erosion) when deciding on the level of precautions required," which requires organizations to be aware of all hazards, including corrosion, that can affect integrity.

Additional pressure on senior management in some sectors came with the introduction of legislation such as the UK Corporate Manslaughter and Corporate Homicide Act<sup>17</sup> that came into effect in 2008. A company, including senior personnel, may be guilty of this new offence if the manner in which its activities are managed or organized causes a death and amounts to a gross breach of a relevant duty of care owed to employees, the public or other individuals. If found guilty, unlimited fines and remedial orders may result, possibly affecting the viability of an organization. The challenge for industry arising from these legislative drivers is to demonstrate to the licensing authorities that the equipment is operating under safe conditions, while from a business perspective continuing to operate cost effectively, often under more aggressive conditions, and in some cases, to extend the life of aging facilities.

The impact of these drivers on engineering and safety procedures has been to focus them increasingly on failure modes likely to affect asset integrity, particularly those giving rise to catastrophic incidents such as corrosion related failures. Typical industry-centered documentation includes the American Society of Mechanical Engineers (ASME) Risk Based Inspection – Guideline Development,<sup>18</sup> the US Pipeline Safety Act,<sup>19</sup> which places emphasis on risk management and cost benefit, API 580 Risk-Based Inspection<sup>20</sup> plus the accompanying resource document API 581<sup>21</sup> and the DnV Risk Based Inspection of Offshore Topsides Static Mechanical Equipment.<sup>22</sup> The Australian/New Zealand Risk Management Standard<sup>23</sup> first published in 1995 provides an excellent basis for evaluation/management of business risk. In this context, New Zealand has also been at the forefront in total asset management, particularly public infrastructure legislation<sup>24</sup> and the publication of guidance.<sup>25</sup>

Risk management is only one of the tools employed to mitigate corrosion and, for example, risk-based inspection (RBI) must be backed up with management of change procedures and end of life strategies. Thus if the compositions of process fluids change or the operating conditions are modified then corrosion assessments must be carried out again for these new conditions. Ageing infrastructures and facilities need increased inspection frequencies and

monitoring to ensure safe operation and this has implications for the allocation of resource for teams concerned with asset integrity and maintenance. Corrosion expertise is a relatively scarce commodity, particularly in management functions. Burdekin,<sup>26</sup> in a review of risk/integrity aspects of materials in 2000, noted that, although quantitative risk assessment for creep and corrosion is still in its infancy, RBI is becoming well established and engineers/materials scientists should have a basic grounding in risk assessment and the principles of reliability analysis since these will become a key basis for decisions.

The prevention of failures requires management systems that incorporate appropriate tools (procedures, risk assessments, and probabilistic methods) and teams (design, corrosion, inspection, maintenance, stakeholders) to develop and implement corrosion management strategies. This is achieved by the incorporation of best practices from Total Quality Management (TQM) as outlined in the ISO requirements for quality,<sup>27,28</sup> health and safety<sup>10</sup> and environmental<sup>29</sup> management systems. The major focus of this chapter is the development, implementation, and maintenance of risk-based management systems to ensure that corrosion mitigation strategies are in place and that mitigation practices are implemented in an effective manner. The chapter provides a framework that may be used to review, audit and continuously improve corrosion management systems. The framework highlights the need for organizations to develop performance standards or key performance indicators (KPIs) to monitor the effectiveness of day-to-day activities during the design, construction, and operation and maintenance phases of projects.

#### 4.30.1.4 Basic Concepts

A corrosion control strategy is defined here as the management of available resources, including finance, materials, equipment and manpower, to provide the policies, procedures and organizational systems that are required to mitigate the effects of corrosion. Successful management strategies provide the means of achieving corrosion control objectives, such as optimal life-cycle costs, minimal leaks and the required life. It is in strategy development and/or in day-to-day implementation of policies that difficulties often appear in the field (essentially the control of who does what, where and when). Effective strategies are typically concerned with long-term objectives and encompass standard corrosion control procedures/established engineering practices that form the basis

for written documentation appropriate for the project under consideration.

Corrosion control tactics can be summarized as the practice or implementation of planned procedures and courses of action necessary to achieve the required corrosion mitigation results. These require guideline documentation and background information for managers and engineers responsible for implementation of corrosion engineering procedures. The basic principles have been in place for decades and have been incorporated into industry practices by embedding them in design reviews and audits, hazard and operability (HAZOP) studies, integrity and operational practices. Fundamental requirements are that equipment is designed, constructed, operated, and maintained in an economic and safe condition.

Tactics involve specific solutions such as the use of corrosion control options and corrosion inspection/monitoring practices to solve particular problems and they are often delivered by specialists and/or contracting companies. The successful implementation of corrosion control options, either singly or in combination, requires not only the production of clear specifications and work instructions but also adequate management structures for the control and reporting of work. Regular reviews and audits are needed to maintain compliance with policies, standards, and company guidelines and also ensure continuing improvement to meet increasingly stringent SHE requirements. This is achieved by development and implementation of performance standards.

Performance standards or KPIs are the basis for planning and measuring achievement. In a practical sense, they are checks that are developed for all levels of the organization and used to ensure that appropriate actions are carried out as required. Setting the appropriate standard is crucial for effective implementation of policies. KPIs are agreed performance criteria that enable the performance of management systems, individuals and day-to-day actions to be judged against acceptable in-house standards and/or industry benchmarks. Failure to achieve the performance standard should trigger a review to identify reasons for under-performance, for example, inappropriate reporting methods, insufficient resources, slow response, and unrealistic KPI. Where appropriate, modifications should then be made to improve performance. The key questions are:

1. Who is responsible?
2. For what?
3. When?
4. With what expected results?

Management KPIs cover the monitoring and measurement of performance of the corrosion management system itself, and not the monitoring/measurement of corrosion which would be subject to separate KPIs. Improvements in corrosion management systems result from the constant reexamination and incorporation of learning from previous performance deficiencies.

## **4.30.2 Corrosion Management Processes**

### **4.30.2.1 Introduction**

In most organizations, capital investments and production activities are undertaken as projects with well defined boundaries and clear business objectives. Managers and teams are usually aware of corrosion as one of many potential threats to project viability but systematic evaluation with regular updates is required so that risks are formally identified and actively managed. Management is a process that should have clearly defined steps with appropriate means of ensuring adequate control of the process. Adoption of a risk-based approach to the corrosion management process can help to align corrosion mitigation practices with recognized good practices, worldwide, and corrosion management processes are likely to be more effective if based on recognized quality management processes.

### **4.30.2.2 Quality Management Processes**

Any process, including a management process, is a series of steps that convert inputs into outputs. For example, a manufacturing process converts raw materials into products, whilst a corrosion process converts metallic items into corrosion products. This process approach, as summarized in the quality management system document ISO 9001:2008,<sup>27</sup> requires organizations to identify and manage numerous linked activities with the output from one process directly forming the input into the next if the functions are to be effective. The ISO standard focuses on an organization's ability to meet customer requirements of a product or service and also addresses both regulatory and the organization's own requirements in terms of quality management. It provides a benchmark for the development and application of corrosion management processes through which in-house or contractor corrosion teams can provide cost effective, corrosion mitigation products and services.

Adoption of basic 'quality' concepts is also important if a corrosion management system is to interface with an existing asset management system especially if it is to be provided by, and/or operated through, an external contractor. The linked standard ISO 9004:2000<sup>28</sup> has been designed to complement ISO 9001:2000<sup>27</sup> but here the emphasis is on senior management inputs in order to achieve continual improvement of performance. Managements inevitably change within organizations and the effectiveness of corrosion management processes will vary with time without the emphasis on 'continuous improvement' that is implicit in most quality management systems. Quality systems complement requirements in technical specifications and provide an auditable trail of documented quality measures and checks.

In general, the aim of a quality approach is to establish, document, implement and maintain a management system and continually improve its effectiveness. The organization needs to:

1. Identify the management processes.
2. Determine the sequence and interaction of these processes.
3. Determine the criteria and methods of operation and control.
4. Ensure availability of resources and information necessary to support the operation and to monitor these processes.
5. Monitor, measure, and analyze these processes.
6. Implement the actions required to achieve planned results.

The functional inputs and steps required in a successful management process are derived from inputs from teams (stakeholders), use of appropriate tools (risk assessments, monitoring methods, etc.) and well defined systems (organizational structures, reporting routes, etc.).<sup>30</sup>

Corrosion management processes can therefore be envisaged as shown in [Figure 1](#).

Teams involved in the corrosion management process during the various stages of a project may be drawn from a variety of functions. Team leaders will be selected on the basis of tasks to be undertaken, skills, and experience of the personnel and the specific stage of the project. Few organizations are large enough to justify the employment of a full time corrosion engineer. Many decisions related to corrosion issues have to be made by managers on the basis of reports and recommendations from design, production, inspection, and maintenance personnel and most operational/day-to-day corrosion mitigation

**Figure 1** Corrosion management requirements.

activities are undertaken by members of the design, process/plant engineering or maintenance teams or contractors. For example, an electrical engineer often becomes responsible for cathodic protection (CP) systems, the site chemist or process engineer oversees the inhibition and biological control of cooling systems, chemical treatment programs, etc. Off-site specialists or consultants provide any required additional support. In general, during the operational phase, an on-site engineer or manager has to interpret field data to identify trends that are required to provide management information.

Tools used as part of corrosion management strategy development encompass corrosion risk assessments that may include risk matrices, and/or probabilistic analyses. Implementation of tactics involves use of corrosion control methods, employment of various corrosion inspection/monitoring techniques to obtain plant/field data, use of data storage, data analysis and trending to convert data into information for decision makers. The development and use of KPIs and risk control systems are tools for the control of operations and day-to-day activities.

Systems for corrosion management are used to implement corrosion mitigation strategies and tactics through well defined organizational structures. Such structures should be based on quality management principles and be clearly laid out on, for example, a flow sheet that highlights identifiable policies/objectives, notes the allocation of responsibilities, resources and the means of corrosion mitigation implementation through procedures that are regularly reviewed and audited. Systems may be paper- or computer-based.

#### 4.30.2.3 Risk Management Processes

Corrosion is a risk to a project/operation and it is therefore appropriate to consider the benefits of well established risk management approaches especially as, for example, one source<sup>31</sup> identifies three levels of decision making in any project:

1. *Strategic decisions* include establishment and confirmation of goals, means, and constraints, identification of key risks and stakeholders plus setting these in context for tactical and operational decisions for each project/activity.
2. *Tactical decisions* involve choosing how to deploy the most appropriate means of achieving goals and managing tactical risks within the restraints set at the strategic level.
3. *Operational decisions* are concerned with implementing tactical choices and managing operational risks. A key element throughout is the development and implementation of written procedures.

Risk management is an iterative process of well-defined steps:

Risk identification → Risk analysis → Risk evaluation → Risk treatment.

When taken in sequence, these steps give rise to improved decision-making by providing greater insight into risks and their impacts on the operation. Two main outcomes from adoption of a risk management approach are:

1. Significant undesired or unexpected outcomes can be identified, and
2. Opportunities for improvement can be considered.

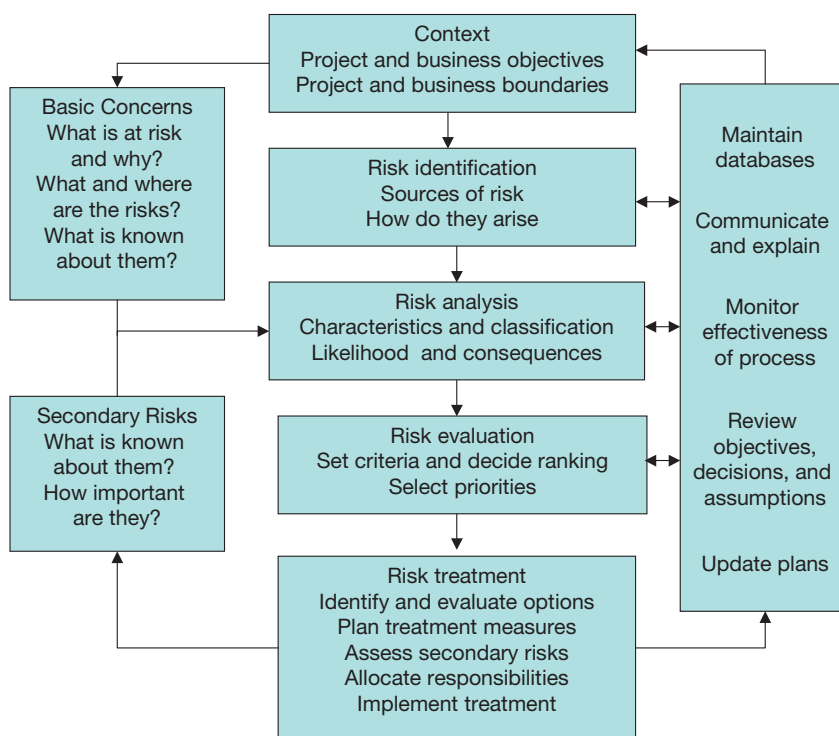

A useful framework is shown in the flow sheet in **Figure 2** that identifies the main issues associated with a risk management process.<sup>31</sup> The specific approach adopted will vary depending on the type of project/industry/business requirements but a key element in all situations is the feedback required to maintain the system. The key features are:

1. *Risk assessment process* – identification, analysis, and evaluation of the risk, its likelihood and consequences, plus criteria used to quantify the risk and priorities to be set.
2. *Risk treatment* – selection of the mitigation options, planning of treatment measures and allocation of responsibilities/implementation of procedures.
3. *Secondary risk identification* – identification during the analysis, evaluation, and treatment process of such risks that are a key factor of any protocol and an important consideration when mitigation of corrosion risks is addressed.

Corrosion risk management must be integrated into the organization's philosophy, practices, and business plans and not viewed as a separate activity. In this context corrosion, management should be focused on

the management of corrosion risk mitigation, that is, strategies and control of day-to-day activities rather than just specific tactics of corrosion control and corrosion inspection/monitoring that are merely the tools used in the mitigation process. Opportunities for improvement and benefits that are inherent in a risk management process are often neglected during the initial implementation of corrosion risk management because of an over-emphasis on risk mitigation. In addition, secondary risks relating to risk mitigation are often neglected, such as:

1. *Inspection risks* – criteria used to determine appropriate inspection methods and the selection of inspection frequencies appropriate for the type of corrosion damage must be understood and their applicability maintained. Loss of corrosion inhibition/chemical treating may result in a higher risk as it negates the basis used for inspection scheduling.
2. *Chemical treating risks* – caustic dosing/corrosion inhibition requires that the process fluids are monitored to ensure compliance to an agreed pH or inhibitor residual concentration. Injection equipment must therefore be maintained to an

**Figure 2** Risk management process, adapted from BS 6079-3:2000.

agreed level of reliability, otherwise the basis of the overall inhibition risk mitigation process and inhibitor availability criteria may be invalidated.

3. *Use of corrosion resistant alloys (CRAs)* – provides protection against general corrosion but will risks from pitting and cracking occur if process conditions change? Are fluid compositions and temperatures monitored to meet agreed upon criteria?
4. *Use of coatings/CP* – requires regular inspection/monitoring and maintenance. Are appropriate checks and regular audits made to ensure corrective actions are carried out?
5. *Design detailing aims* – to eliminate risks from local fluid chemistries/temperatures, equipment/component stresses, fluid flow/heat transfer characteristics, location/layout/geometry of equipment and components; requires reviews and audits.

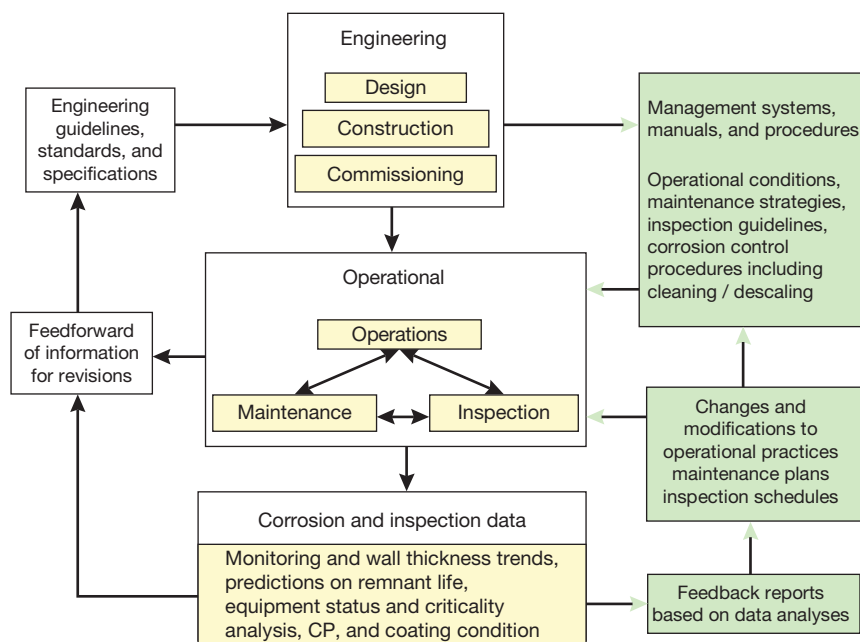

Selection and application of any corrosion risk mitigation plan requires decisions to be made, responsibility allocated and reporting routes established. An audit of mitigation procedures is required before implementation is finalized. Feedback control from information derived from field data and involving comparison with agreed upon criteria and possibly information held in other company databases (production and maintenance) is needed. Also required is

the effective monitoring of the management process, including regular reviews and update of plans. For example, every company standard and procedure should have a written agreed review date in a similar manner as is used in the maintenance of, for example, NACE and ISO standards.

An illustration of the complexity of the corrosion risk management challenge in a multidisciplinary activity can be seen in the flow sheet in **Figure 3** that summarizes typical information flows, including feedback, that are required to mitigate corrosion risks within organizations in the oil industry.

There is already significant technical feedback information within the industry on corrosion issues, but as Milliams has noted,<sup>32</sup>

The management of corrosion is a concern which extends beyond the responsibilities of corrosion and materials engineers. Whilst they should provide advice during both the design and operational phases, they are dependent upon the co-operation of other disciplines if an installation's projected design life is to be achieved. The model proposed provides a framework for that co-operation and for optimizing the contribution the corrosion and materials engineers make to an organization.

**Figure 3** Information flows for the management of corrosion. Adapted from Milliams, D. In 12th International Corrosion Congress on Corrosion Control for Low Cost Reliability 19–24 September 1993; NACE International: Houston, TX, 1993; Vol. 4, pp 2420.

In general, corrosion risk assessment, the identification, analysis, and evaluation of corrosion risks, and corrosion risk treatment, the mitigation of the corrosion risk, are two separate steps in the corrosion management process. Both steps can involve the consideration of secondary risks incurred by the assessment or treatment processes but there must also be an acceptance that not all risks can be eliminated and contingency plans will be needed. For example, in RBI, a premise is that risk of failure can be assessed in relation to an acceptable level or probable annual frequency provided that the damage mechanism and process conditions are known. Eventually repair and/or replacement will be required (condition-based maintenance) but the consequences of a potential failure before that stage must be addressed. A third step is to use agreed upon procedures to monitor and modify the management process. These steps are shown in the summary flow sheet in **Figure 4**.

The success of corrosion management processes used to convert risk inputs into mitigation outputs are largely dependent on the management systems adopted (organizational structures, document systems, information flows, data management systems), the tools employed (risk assessment and mitigation procedures, field data collection, control tactics) and the composition of the corrosion teams.

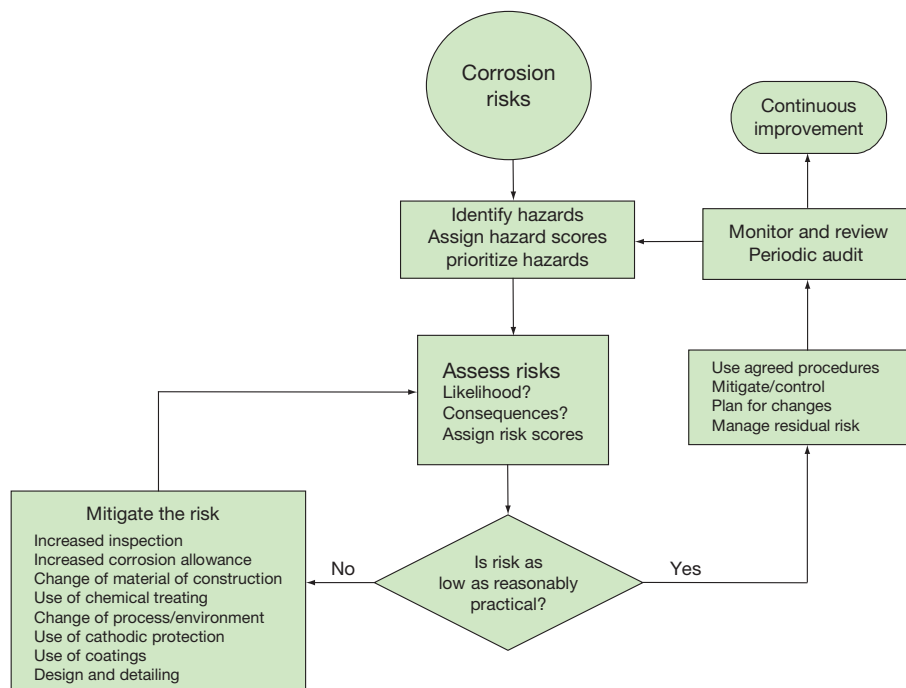

### 4.30.3 Corrosion Management tools

#### 4.30.3.1 Identification of Corrosion Risks

##### 4.30.3.1.1 Corrosion damage and failure modes

The starting point of any assessment is the identification of the corrosion process or corrosion damage that may be sustained by structures/equipment and the impact that this damage may have on integrity and plant operation,<sup>33</sup> including side effects such as the fouling of equipment (sludge in lines/vessels, radioactive build-up in heavy water reactors, strontium scales in oil production) or on contamination of products (food and pharmaceutical chemicals). The various types of corrosion are described in detail in separate chapters in this volume. The more common examples of corrosion damage are:

1. *Uniform corrosion* – metal loss due to general corrosion, atmospheric corrosion/rusting, metal wastage in process streams/cooling water pipe work.
2. *Galvanic corrosion* – accelerated localized corrosion due to the effect of mixed metal combinations or compositional/metallurgical factors as in the corrosion of weldments.
3. *Localized attack* – pitting and crevice corrosion, often the result of a small area of damage in the

**Figure 4** Overall corrosion risk analysis, mitigation, and control process.

protective/passive corrosion product film (small anode area and a large cathode area).

4. *Flow induced corrosion – erosion corrosion, cavitation, impingement attack*, the result of high fluid velocities/high wall to fluid shear stresses/high turbulence intensity, changes in fluid pressure and the presence of second phases such as bubbles and sand.
5. *Environmentally assisted cracking* – caused by the combined action of a mechanical load/tensile stress/residual stresses plus a specific corrosive environment/temperature on a susceptible alloy (essentially a brittle type failure in a normally ductile material).
6. *Corrosion fatigue* – combination of cyclic stresses and exposure of a susceptible metal to a corrosive environment.

Many reports and texts refer to corrosion damage or morphology, or the various forms of corrosion as corrosion failures but in the strict engineering sense, a failure occurs when an item, component, or unit does not meet the design/operational requirements. In this strict sense, corrosion *per se* is not a cause of failure but rather is a contributor to a failure mode that is the combination of the effect of damage on operational (and accidental) loads,<sup>34</sup> as summarized below:

<i>Failure mode</i>	Local leakage Rupture/severance Collapse or buckling
<i>Corrosion damage</i> (corrosion morphology)	Uniform corrosion and isolated pitting Flow induced corrosion & erosion Longitudinal and transverse cracking
<i>Loads</i>	Pressure (internal and external) Forces (tensional/hoop stresses, compressive, bending/torsional) Impacts (collisions, dropped objects)

Likely failure modes are key inputs into engineering risk, or criticality assessments. In most industrial situations the deteriorated condition that may lead to the undesirable leak or rupture, can usually be anticipated by a risk assessment for the specific damage mechanism. In the case of corrosion, this would be based on credible rates of deterioration obtained, for example, from internationally accepted and

published values/mechanisms, and/or identified by on-site corrosion inspection.

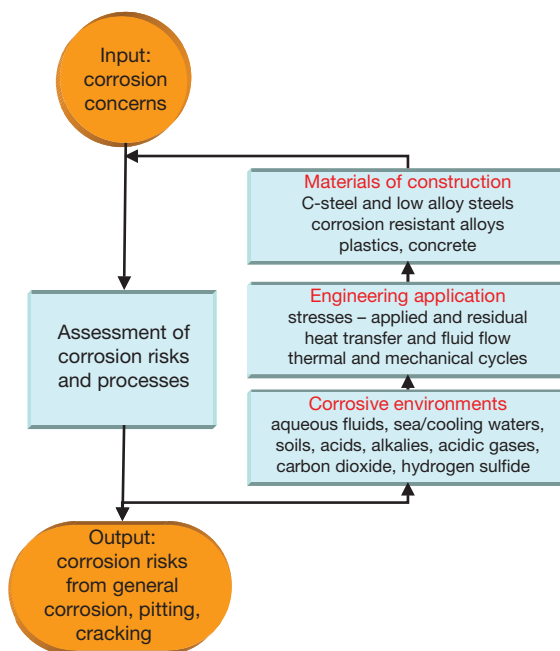

Most assessments concentrate on corrosion that occurs to equipment during its operation but significant damage may also take place during construction and storage of items, start up/shut down periods (when conditions vary from the design basis) and maintenance activities. This requires an understanding of all the factors that may affect probable corrosion processes and cause equipment damage.

#### 4.30.3.1.2 Sources of corrosion risk

Assessments of corrosion risks to either an existing or proposed new equipment start with the consideration of the corrosive environments, both internal and external, to which the equipment is likely to be exposed. The combination of the metal's environment and the influence of engineering factors, such as mechanical stresses, heat transfer and fluid flow, may play a crucial role in the corrosion processes, and will also have to be assessed. In a detailed study each item of equipment (vessel, reactor, heat exchanger, etc.), process stream compositions and temperatures (in and out) and connecting pipe work (including sections of the same pipe run of differing diameter) will have to be assessed.

Therefore, any corrosion risk assessment has to, at some point, consider a combination of three basic influences that control the physical/chemical processes that result in possible corrosion damage, as shown in **Figure 5**:

1. *Materials of construction*, in particular their compositions, fabrication, and required lives: There are many options, depending on the specific requirements. Along with resistance to corrosion and wear, the materials may have to withstand high temperatures, perhaps in the creep range of the material, or low temperatures where brittle fracture is a concern, as may occur during a high pressure gas leak.
2. *Corrosive environments* that vary widely depending on the application and may involve exposure to gaseous atmospheres, naturally occurring or treated waters, acids or alkalis: Some aqueous environments may contain bacteria that produce local highly corrosive conditions whilst some fluids may contain specific salts, for example chlorides and/or sulfates that cause pitting/stress corrosion cracking. Both internal and external and transient conditions, such as are associated with start up and shutdown of equipment, have to be considered.

**Figure 5** Basic corrosion risk assessment steps.

3. *Engineering application*, specifically the type of equipment, its functionality and associated influencing parameters such as exposure to various mechanical loads, fluid flow and heat transfer conditions that can have significant impacts on corrosion processes. Residual and applied stresses can introduce risks of corrosion fatigue and environmentally assisted cracking processes. Fluid flow conditions involving changes in direction, diameter, topography, etc., can cause areas of stagnation, stratified/slugging flow, or high turbulence intensity downstream of protrusions/restrictions/expansions that can introduce risks of erosion corrosion or even cavitation damage. Heat transfer rates and surface temperatures in equipment can result in problems associated with condensation, scaling, fouling/bio-fouling and high temperature corrosion.

Each of the above may contribute in varying degrees to the overall risk. A corrosion risk assessment of a conceptual design would probably concentrate on major specific risks as posed by the initial material selections, such as comparisons between low alloy steels and corrosion resistant alloys (CRAs). A detailed assessment, as employed for RBI scheduling would require each item of equipment to be itemized and evaluated for internal and external corrosion using a formal and audited approach.

#### 4.30.3.2 Corrosion Risk Assessment Processes

##### 4.30.3.2.1 Hazards and risks

Identification of hazards and assessment of risks are fundamental steps in corrosion mitigation and engineering studies. The relationship between hazards and risks emerges from their definitions:

1. A *hazard* has the potential to cause harm or damage; often defined as a physical condition or release of hazardous material as a result of component failure that can cause human injury or death, loss or damage, or environmental degradation.
2. *Risk* is the combination of the severity of the effect (the consequences) and the likelihood of it happening (damage mode and probable frequency).

The tools used to identify, analyze, and evaluate corrosion risks and then to treat or mitigate those risks vary considerably depending on the specific application. Identification and ranking of hazards and risks associated with corrosion lead to prioritization of actions, use of framework rules with guidelines/protocols and assessments of how corrosion and asset integrity systems are managed.

The assessment can be either paper-based or carried out using appropriate software on a PC-based system depending on the complexity of the facility. In its simplest form, it is a careful engineering examination of the items comprising a facility and the likely corrosive environments, the materials of construction and engineering application. For example, for a port or harbor facility a major concern would be the marine environment and ambient temperatures for specific items, for example the effects of anaerobic subsoil/mud, seawater, tidal/splash zones or saline atmospheres as appropriate on sheet steel piles and columns (possible ice flow abrasion?), reinforced concrete beams, pillars and mooring dolphins, storage sheds, cranes, lifting gear, etc. The effectiveness of existing or proposed corrosion control measures such as coatings, CP, and even chemical treating of vehicle cooling systems should be considered based on previous experience, existing maintenance, and published data records.

In general, the information needed for corrosion assessment includes a list of items of interest from the asset register (structures/vessels/pipework/storage tanks, etc.), historical data (inspection/monitoring/maintenance), theoretical analysis (new systems based on published data/models), informed opinions

and concerns of stakeholders (individuals, groups, other areas of the organization) and field data where available. Such risk assessments are the tools that focus attention on critical areas and they are used to review a design, ensure asset integrity and improve corrosion control but do not by themselves provide management control. Outputs from risk assessments are recommendations that may include changes to the inspection/monitoring or use of/change of the corrosion control practices. The decision-making steps form a vital part of the management process.

At its simplest, the assessment is a common sense engineering approach that provides a means of checking on what is often a good existing practice. Decisions are based on questions such as:

What would be the worst case scenarios?

1. How likely are they to occur?
2. What would be the damage?
3. How many people could be injured or killed?
4. How will these events affect the business?

The three fundamental questions in corrosion risk analyses are:

1. Failure mode – what could go wrong?
2. Failure effect – how will it affect the project/plant integrity/operations?
3. Failure criticality – how likely is it?

Criticality analyses examine potential failures to assess the severity of each failure in terms of decreased performance, total loss of function, safety, and environmental hazards. Typical steps in such an assessment include:

1. Identify plant components (Tags) or process function.
2. List possible failure modes for each component (Tag number).
3. Identify likely effects of each failure mode.
4. List all possible causes of each failure mode.
5. Assess the failure modes numerically (e.g., on a scale of 1–10).
6. Evaluate a criticality index for each failure mode to assess priority of failure mitigation/prevention actions.
7. Indicate required corrective actions, expected completion date, and the departments/people with required responsibility.

The first step is therefore to consider potential hazards/escape of flammable gasses/liquids/toxic substances and the effect on people/the environment and the business. This focuses attention on the items at risk

and the approach could be similar to the procedures that are used in the process industries to identify hazards and operability issues (HAZOP). In general, a corrosion risk assessment will incorporate appropriate findings from HAZOP/environmental studies for the evaluation of likely consequences as indicated below.

With hazardous or toxic fluids such as hydrocarbons and other chemicals the effect or consequences criteria of a failure depend on stored energy ( $E$ ), pressure ( $P$ ), volume ( $V$ ), toxicity ( $T_x$ ), flammability/explosive risk ( $F$ ), and temperature ( $T$ ). An overall hazard score  $H$  can be allocated:

$$H = E \times P \times V \times T_x \times F \times T$$

for each vessel, tank, piping system or other equipment items. Safety risks may be scored on the severity of the possible incident and number of people likely to be affected (<3, 3–9, >10). The effect of any failure is typically considered in an environmental impact study and the economics addressed by estimating the effects of shut down (partial/full) on the operations and time required to effect repairs. All risks are multiplied. A quantified (Level 3) assessment of an item depending on the numerical values chosen for the likelihood and consequences criteria, for example an oil/gas pipeline, could provide a total numerical score as follows (Table 2):

The criteria employed in any risk assessment are often based on judgment and agreed upon guidelines and are not absolute; therefore, a degree of skepticism is always helpful when the criteria adopted in the assessment are not specified.

#### 4.30.3.2.2 Matrix analysis

In many engineering studies, the criticality of an item is presented as a table or matrix of the likelihood of failure against the effect of a failure:

Criticality = Likelihood of failure  $\times$  Effect of failure

Most corrosion risk assessments are qualitative using a judgment, based on descriptive ranking such as

**Table 2** Risk score based on likelihood and consequences

Total score	Criticality ranking
<300	Low
301–1000	Moderate
1001–3000	High
3001–10 000	Very High
>10 000	Extreme

high, medium, or low that may be converted into a simple numerical description. For particularly critical equipment, for example in the nuclear industry, a rigorous quantitative analysis is adopted:

$$\text{Risk} = \text{Probability} \times \text{Consequences}$$

The outcome is a numerical value, with measured units, that may be simplified by assigning bands to the probability and consequences.

Corrosion risk assessments can be typically classified into three groups:

Level 1 – Qualitative risk analysis, a simple ranking of equipment

Level 2 – Semiquantitative risk analysis, a more accurate prioritization that retains vital inputs of a Level 3 analysis but simplifying assumptions

Level 3 – Quantitative risk analysis, an in-depth study including assessment of reliability, financial and limited environmental issues

Failure mode, effect, and criticality analysis (FMECA) is an example of an engineering risk evaluation process that has been used for over 40 years to evaluate systems, including those on commercial jet aircraft. The analysis considers the seriousness/consequences of a failure (*S*) and the probability (*P*) of the occurrence of each failure mode. The analysis may also include the difficulty of detection (*D*) of the failure mode/damage. Table 3 indicates that corrosion damage that may have a high rate of penetration such as stress corrosion cracking or corrosion fatigue which is the most difficult to detect by inspection,

**Table 3** Characteristics of corrosion damage

<i>Damage</i>	<i>Ease of detection</i>	<i>Rate of penetration</i>
Uniform	Very high 1	Low
Pitting	High 2	Medium
Erosion	Medium 3	Medium
Cracking	Low 4	High

**Table 4** Criticality index (FMECA)

Probability ( <i>P</i> )	Rare 1	Unlikely 2	Moderate 3	Likely 4	Almost certain 5
Seriousness ( <i>S</i> )	Not serious 1	Nuisance 2	Repair 3	Change 4	Shut down 5
Detection ( <i>D</i> )	Easily detected 1	Medium 2	High 3	Detection unlikely 4	
Criticality ( <i>C</i> ) (Ranking value)	Low <20	Medium 20–60	High >60		

whilst the easiest damage to detect, general corrosion, is the simplest to manage by basic trending of inspection data, for example loss of corrosion allowance with time.

In a simple corrosion or maintenance situation (i.e., using a common sense engineering assessment) a basic paper-based corrosion risk assessment (level 1) may be employed with the probability and consequences judged either high/unacceptable or low/acceptable. Alternatively a numerical value can be assigned (5 – low, 4 – medium, 3 – high, 2 – very high, 1 – unacceptable). The advantage of developing an agreed numerical ranking, as is employed with some visual inspections of equipment or paint deterioration based on the degree of rusting of coated surfaces,<sup>32</sup> is the ease of handling data input/output in computer systems.

Such a ranking is illustrated in the criticality index (*C*), shown in Table 4, which provides a numerical ranking ( $C = P \times S \times D$ ) that enables a risk assessment team to focus on items of a plant, or processes, that have varying levels of corrosion risks. In this particular example, the following values have been arbitrarily assigned:

Probability and seriousness	between 1 and 5
Detection	between 1 and 4
Overall criticality rank of items	between 1 and 100

A more common approach to risk assessment is the use of risk matrices for evaluating various probabilities and consequences as illustrated in Figure 5 developed as a simple corrosion risk matrix for the assessment of corrosion mitigation options for reinforced concrete. Corrosion processes in reinforced concrete are described in a separate chapter in this book. Reinforced structures, including those constructed with good quality concrete, are susceptible to rebar corrosion damage resulting from carbonation and chloride ion ingress from marine/ground waters.

Chlorides in the presence of high levels of oxygen cause pitting of rebar and the corrosion spreads to give rise to high rates of general corrosion. The buildup of corrosion product causes the concrete cover to crack leading to increasing rates of attack. This is a particular problem in hot climates where the high temperature of cure increases concrete permeability and subsequent chloride penetration rates. Structures constructed in hot saline regions therefore have an increased risk of pitting/corrosion of rebar.

Practices that mitigate the effects of chloride ingress in concrete include:

1. use of coatings on the rebar;
2. use of sealant/coating on the concrete above grade;
3. use of waterproof membrane to prevent water ingress into foundations;
4. application of CP, retro-fitted to existing corroded concrete structures or designed into new structures.

The preferred choice depends on the particular situation and the life cycle costs for each option. Life cycle assessments should include the likely costs of future repairs and any associated downtime. The option of not including extra corrosion protection (reliance on concrete cover only plus probable maintenance/repair costs) should also be assessed as the base case.

The development of a simple risk or criticality ranking for reinforced concrete structures based on a  $3 \times 3$  matrix analysis is shown in Table 5. The actual criteria used, Table 6, can be adjusted with experience. This approach essentially encompasses information in a number of international standards on concrete construction. However, these tend to underestimate corrosion risks in marine situations, particularly at high ambient temperatures and saline contents.

Table 6 illustrates the use of 'rules' or agreed-upon criteria to define the likelihood of corrosion, the effect of corrosion and the final ranking. A major

risk factor is not only the technical and corrosion issues but the effect of future repairs and downtime on life-cycle costs as well. The results of the risk assessment could also form the basis of a mitigation strategy and development of agreed upon procedures as shown in Table 7, the success of which depends on the management of associated risks.

The above example illustrates the principle of matrix analysis but other risk assessment systems use  $4 \times 4$ ,  $5 \times 5$ , or  $4 \times 5$  matrices, with either linear or logarithmic scales with output as a numerical risk

**Table 6** Typical guidance for reinforced concrete structures

<i>Likelihood of corrosion</i>	
High	Concrete contains chlorides. Average/low cover. Tidal marine zone, sabkha region ground waters, waste water pipes.
Medium	Atmospheric marine environments/wind-blown sabkha sand. Possibility of regular wetting from water spills.
Low	Office environments, aggregates and mix water had low chloride levels. Design mix and placement to standards.
<i>Effect of corrosion</i>	
High	Rapid corrosion/cracks/spalling in <10y which prevents facility use. Repairs are costly because of access.
Medium	Repairs in 10–25 years. Facility unavailability tolerable for repairs, Accessibility reasonable nor expensive
Low	No significant effect <25 years, availability not critical. Easy access/low scaffolding costs. Simple patch repairs OK
<i>Risk/criticality ranking</i>	
1	Use existing codes for concrete and cover thickness. Remedial works unlikely to include coatings/CP.
2	May consider sealant or anticarbonation barrier coating for new designs
3	May consider inhibition or coated rebar for new designs, Corrosion damaged structures consider realkalization/chloride removal
4	Additional corrosion protection is likely for new designs, Retain option to retro-fit CP. Repairs should consider realkalization/chloride removal followed by either sealant coatings or retro-fitting CP at later date.
5	Extra corrosion control should be mandatory with new designs. Repairs/refurbishment should consider CP option

**Table 5** Example of a simple risk or criticality ranking for concrete structures based on a  $3 \times 3$  matrix analysis

<i>Criticality ranking, 1–5</i>				
Effect of failure	Low	1	2	3
	Medium	2	3	4
	High	3	4	5
		Low	Medium	High
		Likelihood of failure		

**Table 7** Selection of corrosion control options for concrete

Marine structures (chlorides, atmospheric oxygen)	Cathodic protection in tidal and splash zones Coatings for topsides
Foundations (chlorides, biological compositions)	Water proof membrane/ tanking or cathodic protection in high salt content ground (especially sabkha regions)
Above grade structures (atmospheric exposure)	Sealants or coatings on the concrete. Fusion bonded epoxy coated bar where salt contamination is likely to be high
Inside buildings (controlled environment)	Combination of material selection and conventional design codes

factor. Some are based on the probability of the failure criteria as in the quantified or Level 3 assessment employed by API 580/581.<sup>20,21</sup> Weighted factors may be employed to develop the inputs for the likelihood of failure and consequences of failure.

The purpose of the matrix approach is to prioritize risks and to concentrate efforts on the most influential ones. The numbers on the diagram would typically correspond to threats and opportunities taken from a risk register. A drawback with this approach is that it is difficult to know when the optimum risk mitigation position has been reached unless it is also linked to further actions such as a probabilistic evaluation. However, it is relatively simple and time-efficient to implement. Some of the first practical applications of criticality/RBI methods were on UK North Sea platforms<sup>35</sup> from 1991, and refinery units since the mid-1990s. The approach has been adopted by many operators/service companies/vendors/software suppliers.

#### 4.30.3.2.3 Risk-based inspection

RBI is the subject of a separate chapter in this volume. RBI of process equipment is arguably the most familiar example of how matrix analysis is used in the development of corrosion mitigation strategies at various levels of decision-making. An industry benchmark can be found in the API RBI approach<sup>20,28</sup> that uses a  $5 \times 5$  matrix, **Figure 6**, to identify levels of risk in refinery/process equipment. The output from a quantified (level 3) assessment, as described previously in the determination of hazard scores, is used to determine the consequences category of the matrix.

**Figure 6**  $5 \times 5$  matrix used in the API 581 risk-based inspection procedure.

For example, equipment items at high risk (5D, 5E, 4E, 3E) are unacceptable, requiring a redesign in more corrosion resistant materials or alternative processing routes to be employed. Medium-high risk items could be assessed to see if increased inspection frequencies would allow continuing operation but obviously with a limited life (a predictive maintenance strategy) or if improved corrosion control measures would be effective at decreasing the likelihood of failure and moving the item into a medium risk level and also extending the life. Here a probabilistic analysis could also identify a cost effective option for such strategic decisions.

The resource document, API 581, and the accompanying software package assess consequences (leakage/rupture) for different areas of damage (size of holes in the pipe work and vessels) from general and localized corrosion and cracking. Various scenarios are then evaluated in terms of flammable/toxic effects together with environmental and business interruption effects. The resource document contains a number of technical modules that describe how the potential damage mechanisms are assessed for petrochemical process equipment (from recognized published data) in terms of a damage factor. Key elements of the API RBI approach are:

1. The use of a probabilistic approach for determining the rate of damage, metal loss or crack progression, also employed in the DNV G101<sup>22</sup> offshore inspection standard.
2. The effectiveness of inspection programs in finding and monitoring identified damage mechanisms by assessment of the inspection effectiveness, detection capability of the inspection methods employed and other factors in the inspection process.

Typical inspection methods are ranked, 1–5, in terms of their effectiveness for various forms of damage such as thinning, surface and subsurface cracking and blistering. For example, for general thinning:

1. *Highly effective* (90%) – complete internal visual examination plus ultrasonic thickness testing (UT).
2. *Usually effective* (80%) – partial internal visual examination plus UT.
3. *Fairly effective* (50%) – external spot UT.
4. *Poorly effective* (40%) – hammer testing/telltale holes.
5. *Ineffective* (33%) – external visual examination.

The underlying logic is based on expert opinion quantified using Bayes' Theorem by incorporating the information as a 'State of Damage,' with 1 = equipment damage is no worse than expected based on models/experience, 2 = damage somewhat worse than anticipated/as is sometimes seen in similar equipment, 3 = equipment is considerably worse than anticipated, that is, rarely seen but has been observed occasionally in industry. Combining the inspection ranking with the damage state enables the inspection effectiveness to be quantified to provide a probability ranking.

The software then determines the inspection frequency based on the thickness of the wall, probability of a failure, the damage factor for the type of corrosion (from recognized published data) and the extrapolation of the inspection data trend. When the damage factor increases to a value of 10 or higher after four or more 'highly' effective inspections then the equipment is at the end of its useful life. A value of 10 indicates that the probability of failure increases by an order of magnitude. The aim is to achieve or maintain a low damage subfactor at ideally 1 or less but in practice less than 10, by changing either the inspection frequency and/or the method of inspection (the effectiveness). As the number of effective inspections increase then confidence in the outcome also increases (the error band associated with the measured corrosion rates is decreased), that is, the trend becomes more reliable.

The protocol adopted is illustrated by the effect of progressive damage resulting from general thinning and localized thinning (pitting and erosion–corrosion) on the strength of an equipment item, as shown in [Figure 7](#). The corrosion rate (wall thickness change with time) is determined from inspection data or may be initially obtained from published data and/or industry models and expert opinion. The default/baseline

**Figure 7** Probability of failure with time, adapted from API 581.

position is that the corrosion allowance is 25% of the original wall thickness but this is typically modified by use of the maximum allowable working pressure (MAWP) based on ductile overload calculations, operating conditions, diameter and the material properties, limit state function and the minimum allowable thickness (MAT).

The equipment, for example, begins life with the initial strength exceeding the load by some factor of safety. The damage mechanism progressively weakens the structure but the damage rate is likely to be higher or lower than any deterministic mean value. There is therefore a distribution about the mean value of strength as shown by the dashed lines.

In practice, the applied load will also vary and hence the probability of failure will increase progressively as bounded by the intersection of the two sets of dashed lines. This failure probability is described by an S-curve which, for example, may follow a standard distribution, such as normal/lognormal/Weibull. The intersection of the two solid curves indicates the basis of the equipment design, the constructional material properties, equipment dimensions, etc. and a deterministic corrosion rate. This indicates there is a probability of failure of  $\sim 10^{-5}$  at the required lifetime but also failure probabilities at lower and higher lifetimes. The probabilities of failure adopted for corrosion damage in process equipment are similar to risks in other engineering systems, for example, subsea pipeline as summarized in [Table 8](#).

In summary, the API 581 approach and proprietary RBI software can produce reports for a particular plant item with consideration of the ranking, for example, of three levels of inspection activity:

1. A minimal inspection plan.
2. The current level of inspection.
3. An optimized level of inspection.

The first and obvious outcome is that the inspection frequency can be adjusted, but the methods and tools

**Table 8** Example of an offshore risk category

Category	Probable annual frequency	Description
5 (Failure expected)	$>10^{-2}$	Event expected more than once in lifetime
4 (High)	$10^{-2}-10^{-3}$	Event expected to occur during pipeline life (100-year storm)
3 (Medium)	$10^{-3}-10^{-4}$	Event not expected but a once a year credibility with large number of lines
2 (Low)	$10^{-4}-10^{-5}$	Event rarely expected
1 (Negligible)	$<10^{-5}$	Considered negligible

Annual failure frequency for a pipeline/umbilical (based on DNV – RPF107, 2001).

used for the test and inspection (T&I) schedule can be changed. The scope, quality, and extent of the inspection and data collection/interpretation can also be modified. The benefits are that, the plant items at low risk can be inspected on a less frequent basis than by the more traditional procedures employed previously, resulting in lower inspection costs. There is, however, considerable resource needed to populate the database with the plant inventory, line diagram information and previous inspection history, plus the appointment of an experienced team leader/contractor.

At the tactical level, RBI identifies the specific levels of risk to various process units, vessels, tanks and pipe work or items of equipment and hence appropriate inspection frequencies can be scheduled, the level of resource predicted and maintenance action may be taken to mitigate the corrosion risk. At the operational level the day-to-day activities are determined by the agreed upon schedules and should be implemented by work instructions. At the strategic level, the analysis focuses management attention on corrosion of critical items and asset integrity issues but here the secondary risks resulting from, for example, failure of chemical treating systems or use of inadequate inspection methods must also be recognized by putting in place management-of-change procedures.

### 4.30.3.3 Probability Analysis – Dealing with Uncertainties

The probabilistic approach, which is similar to a reliability analysis, may be used to handle uncertainties in, for example, corrosion related design studies, the use of inhibition schemes or inspection strategies. This management tool assists the decision making process by presenting various scenarios that indicate possible futures. The input, that often includes imprecise data, can be varied to identify the sensitivity of the outcome to parameter changes. Incremental project funding is then only allocated on the basis that there are clear risk and uncertainty statements available at each investment decision point. The quantified output, typically expressed as a probability graph (S-curve), provides a clearer picture of risks and benefits derived from specific corrosion mitigation procedures. Thus although the overall results may be essentially similar to a qualitative judgment based on experience and/or traditional expert evaluation of a system, such subjective decisions are often taken without a full appreciation of the implications of uncertainty and risk.

Prediction of anticipated corrosion rates in a system is the first step in assessing corrosion risks and monitoring requirements. In most cases, information is obtained from published data and models. For example, in oil/gas production a number of predictive models are available for CO<sub>2</sub> corrosion of low alloy steels used in many vessel and pipeline fabrications. Most models are based on preliminary studies of de Waard and Milliams whose initial approach<sup>36,37</sup> was later modified to include the effect of fluid velocity.<sup>38</sup> The similar Norsok model<sup>39</sup> uses the fluid to wall shear stress rather than liquid velocity as the flow parameter. All models provide a single deterministic value of the corrosion rate (single value point data) but a probabilistic analysis shows that this statistical average can have higher anticipated values, for example, a corrosion rate of  $c. 1 \text{ mm year}^{-1}$  could reach a maximum of  $4.5 \text{ mm year}^{-1}$ , depending on the distribution function employed, as shown in **Figure 8**.

A quantitative/probabilistic risk analysis uses random variables described by probability density functions (PDFs) or cumulative distribution functions (CDFs) to describe the various parameters that contribute to the overall process, such as the distribution of corrosion rates indicated above. Density functions describe probability using the area under the curve to the left of the associated value; distribution

**Figure 8** Typical outcome of a probabilistic approach for CO<sub>2</sub> corrosion rates. Reproduced from McMahon, A. J.; Paisley, D. M. E. *Corrosion Prediction Modelling*, BP Sunbury Report, ESR.96.ER.066, November 1997.<sup>40</sup>

functions compare value and probability directly. Various functions that describe the overall process (normal, lognormal, uniform/on/off, triangular, etc.) are then combined together to provide the output, for example survival probability or probable structure life, as shown in Figure 9. Importantly where any parameter is not known, a distribution is used to describe the (credible) range of values that are likely to occur. The outcome of the analysis, typically obtained using a Monte Carlo simulation, as illustrated in Figure 9, is recorded (for example on a histogram/S-curve) and the calculation repeated until sufficient information is generated in order to optimize the smoothness of the shape of the combined S-curve results. In practice, a network is developed to describe the overall process of interest, as indicated in the lower right hand part of the figure, and the variables/data are inserted as inputs with the outputs presented as a series of S-curves that describe various scenarios.

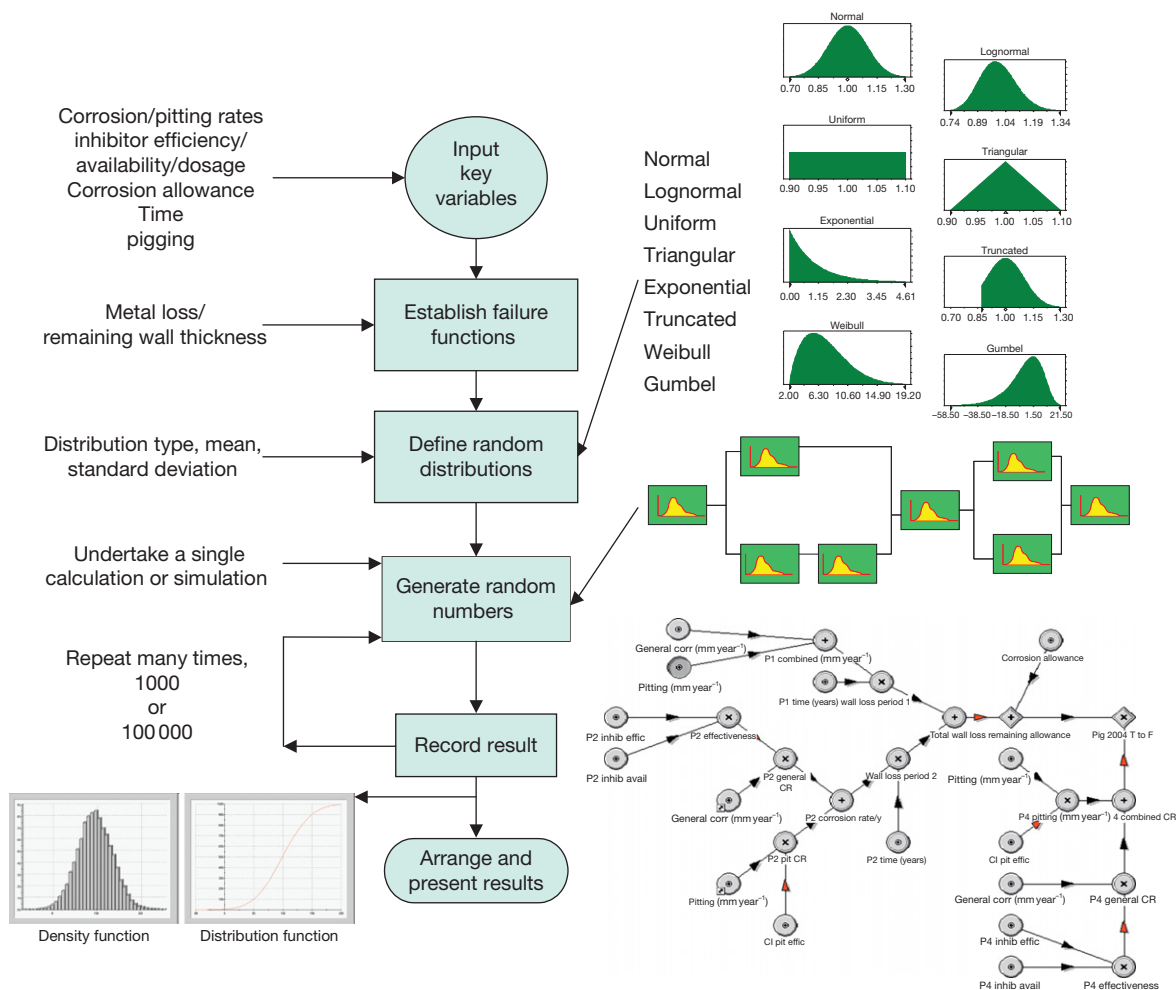

An illustrated example of the probabilistic method is shown in a pipeline pigging study to aid strategic decisions for inhibition and delivery of design life.<sup>41</sup> An off-shore oil pipeline had operated under stratified flow with a corrosion risk to the lower 70% wetted area due to dissolved carbon dioxide and hydrogen sulfide. The line condition after 3½ years of operation was unknown and the requirement was to identify the most cost effective means of achieving a maximum required life. Possible options were to inhibit and to clean by pigging either immediately or after 4 years' time as originally scheduled. The most effective option was determined using propriety decision analysis software developed for business risk modeling.<sup>42</sup>

The line had operated for 2.25 years with no corrosion inhibition (an industry procedure adopted for low water cut systems) followed by 1.25 years with corrosion inhibitor injection, although not always meeting target injection rates. The corrosion damage was likely to be a combination of general corrosion and pitting corrosion, with predicted corrosion rates between 0.05 mm year<sup>-1</sup> due to general corrosion and 1 mm year<sup>-1</sup> due to pitting corrosion with an average rate of 0.6 mm year<sup>-1</sup>. Uncertainty was described for general and pitting corrosion rates by assuming a truncated normal and lognormal distribution curves respectively as given in DnV G101.<sup>22</sup> During inhibition the general corrosion rates would probably have decreased; however, any pits that formed prior to inhibition may not have been fully protected and could have continued to propagate. Minimum, peak (mode), and maximum values were estimated.

Limited UT thickness inspection data from topside pipework at three well heads provided a statistical distribution of corrosion rates that were compared to predicted values using industry corrosion models and a likely distribution of loss of metal obtained:

General corrosion rates	Pitting corrosion rates
Low = 0.15 mm year <sup>-1</sup>	Low = 0.1 mm year <sup>-1</sup>
Medium = 0.35 mm year <sup>-1</sup>	Medium = 0.3 mm year <sup>-1</sup>
High = 0.55 mm year <sup>-1</sup>	High = 0.9 mm year <sup>-1</sup>

Uncertainty in the corrosion inhibition efficiency was described using a triangular distribution as the variables had a limited range and a reasonably good best estimate was shown with some variance on either side as shown in Table 9:

**Figure 9** Probabilistic method as used in a quantitative corrosion risk analysis.

**Table 9** Likely inhibitor performance

<i>Inhibitor efficiency</i>	<i>Inhibitor availability</i>	<i>Efficiency in pits</i>
Minimum = 0.7	Minimum = 0.5	Minimum = 0.1
Peak = 0.8	Peak = 0.7	Peak = 0.5
Maximum = 0.9	Maximum = 0.95	Maximum = 0.9

The following scenarios for the future lifetime of the pipeline with/without pigging and improved inhibition were evaluated:

Scenario 1: Continued operations with no pigging and current inhibitor regime – rate of degradation would continue as previous operational conditions.

Scenario 2: No pigging but implementation of an improved corrosion inhibitor program – Inhibitor efficiency and availability could be increased but

**Table 10** Improved inhibition program

<i>Improved efficiency</i>	<i>Improved availability</i>
Minimum = 0.89	Minimum = 0.94
Peak = 0.9	Peak = 0.95
Maximum = 0.95	Maximum = 0.98

inhibitor ingress into pits is retarded with little effect on protection of pits. The uncertainty in the improved inhibitor efficiency and availability are described in [Table 10](#).

Scenario 3: Pigging in 4 years' time followed by an improved inhibition program – pigging reduces corrosion and corrosion inhibitor is more effective on a 'clean' surface, estimated pitting corrosion efficiency following pigging could reduce corrosion by 90%. This improved inhibitor efficiency in pits was

described by a triangular distribution with the minimum = 0.87, peak = 0.90 and maximum = 0.93.

Scenario 4: Pigging now followed by an improved inhibition program.

The various options were determined using a Monte Carlo simulation and an appropriate network that describes the system with the probable range of outcomes expressed as a probability versus time plot (or *S*-curve), **Figure 10**. The integrity limit was assumed to be loss of corrosion allowance of 6 mm and a minimum allowable wall thickness (MAWT) based on the operational pressure.

The conclusion was that pigging should be carried out at the earliest opportunity to ensure a low level of risk over the next few years. Corrosion inhibition can be effective against pitting but some may perform better than others at inhibiting existing corrosion pits and a comparison of different inhibitors under simulated production conditions could be carried out to select the most appropriate inhibitor. This in combination with pigging should ensure a long operational life.

The above case study illustrates the main points of a quantified approach, that is, that the greater part of the value is realized in risk management by identification and implementation of the most appropriate risk treatment strategies. An expert opinion from a corrosion engineer would be that pigging is recommended when inhibition is employed to mitigate the effects of sludge/pitting corrosion but the graphs

provide the justification for the recommendation and aid management decision-making processes.

The above provides a corrosion mitigation strategy but has to be followed up by development of tactics such as confirmation of the pipeline condition by in-line inspection, magnetic flux leakage detection for wall thickness and estimation of pitting, and tests to assess the effectiveness of inhibitor dosage to control pitting corrosion. A cost benefit analysis, using net present value (NPV) and a discount factor of 5%, of pigging and inhibition versus continuing to operate with the original regime indicated the financial incentive. A failure would be likely to cost \$25 million, an improved inhibitor program \$60k per year and regular (offshore) pigging \$100k per year but these combined are ~21% that of the 'do nothing'/retain the current practice.

The statistical modeling/probabilistic method was extended using commercially available software (@Risk)<sup>43</sup> in a second case study of a sub-sea pipeline network but using an API 570 pipework data trending approach that had been described in a previous publication.<sup>44</sup> The aim was development of a written scheme of examination which provides an auditable trail for each pipeline that clearly identifies corrosion threats and mitigation measures. Remaining life is shown as an inverse *S*-curve that then forms the basis of an annual integrity approach based on available inspection and monitoring data that then defines a technical assessment of the asset condition.

**Figure 10** Probability of failure – loss of 6 mm corrosion allowance.

**Figure 11** Basic corrosion risk mitigation steps.

#### 4.30.3.4 Corrosion Mitigation Requirements

Identification, analysis, and evaluation of corrosion risks form the first steps in the corrosion management process. The next major step, as illustrated in [Figure 11](#), is to provide cost effective solutions to mitigate corrosion risks by the selection of appropriate corrosion mitigation options.

The major tactics used to mitigate the effects of corrosion are embodied in many international/national standards, industry guidance documents, and in-house standards/procedures. These tactics are described in detail in the relevant chapters in this book but can be simplified into the following basic list:

1. *Materials selection* – metallic materials: carbon steels/low alloy steel (usual to include a corrosion allowance during design), CRAs (stainless steel, nickel alloys, titanium), nonmetallic materials (polymers, glass reinforced plastic (GRP), elastomers, ceramics).
2. *Chemical treatments* – typically inhibitors, biocides and scale control chemicals but packages also include surfactants, antifoaming chemicals. Inhibitors used

in boiler and cooling waters, oil/gas production systems and in special concrete designs. Biocides are employed in cooling water systems and hydrotest fluids, water injection/waters systems, whilst scale control chemicals are used in cooling systems, boilers and oil/gas production and process plants.

3. *Use of coatings* – metallic, nonmetallic and organic/paints, used in external and internal environments, major factors are cost, availability, ease of surface preparation, application and life expectancy, important to ensure appropriate specifications, field application and inspection is carried out.
4. *Cathodic and anodic protection* – electrochemical methods of corrosion control. CP can be applied to immersed and buried structures, jetties, pipelines, tanks and concrete. CP is also used inside water containing vessels, tanks and the water boxes of heat exchangers. A low level of protection (cathodic prevention) is used in some concrete structure bridge designs that involve high-strength stressed steel. Anodic protection uses potentiostatic control of the internals of process equipment to ensure that electrochemical passivity is maintained.

5. *Process and environmental control* – modify moisture/humidity levels, lower oxygen concentrations. Change pH, throughput, decrease flow rate and/or heat transfer rate.
6. *Design* – use of codes/standards. At concept/front end engineering stage assess corrosion hazards and risks, evaluate life cycle costs. During engineering design phase use agreed codes and standards to produce specifications and drawings. Introduce QA/QC and inspection/testing procedures into specifications. During the detailing phase assess factors associated with stress, shape, compatibility, and surface condition, for example, eliminate stress raisers, crevices, and consider increased wall thickness on some bends. Use reviews/audits of concept, engineering, and detailing designs.
7. *Inspection and monitoring* – trending of deterioration rates, chemical dosages and changes in process chemistries

The first six options above are corrosion control methods and are used either singly or in combination, the choice depending on the specific application and the corrosivity of local environments. Many of these options are now covered by ISO/EN/NACE standards that are informative and contain guidance and recommendations for suitably trained, experienced, responsible personnel. However, such standards are not specifications or prescriptive and should not be used for certification purposes.

Key issues are reliability<sup>45</sup> and elimination of corrosion risks during the detailed design stage of the engineering design.<sup>46</sup> Design teams should be aware of likely damage as described in, for example, the compilation of photographs of corrosion damage to plant structures for oil/gas production<sup>47</sup> and the required mitigation procedures/audits.<sup>48</sup> The choice of the corrosion control method selected is highly dependent on materials cost, the discount factor/interest rate and life-cycle costs as described in the chapter on corrosion economics in this book and elsewhere.<sup>49</sup> However, as Turner noted in his life time observations on process engineers<sup>50</sup> “a fact of life is that the senior management is to fix the budget for a project as high as it could be to still provide a profit.” The associated economic risk for a project is essentially the uncertainty that may lead to consequential/indirect costs of failures and shutdown/unavailability and the risk management aspect is illustrated in decision tree analysis of expected values for carbon steel and CRA pipeline<sup>51</sup> and probabilistic studies

Consideration has also to be taken of the need to monitor both equipment condition and changes in

plant process fluids. Corrosion inspection and monitoring provide data on materials performance and the effectiveness of chemical treatments, such as corrosion inhibition, that form the basis of corrosion mitigation strategies in some industries. To be effective, any field data must be collected, analyzed, trended, and correlated with other relevant parameters in order to provide information for management to make appropriate decisions. Inadequate or poor field data means lack of information and may lead to inappropriate actions.

Corrosion inspection and monitoring are undertaken with one of two purposes:

1. To determine the condition of equipment and any consequent requirements for repair, and changes in wall thickness and/or rates of localized corrosion or cracking that have implications for future retirement that are prime concerns of asset integrity and maintenance teams.
2. To monitor changes in fluid corrosivity due to damaging excursions in environmental composition and/or to control chemical treatments, such as corrosion inhibitor/biocide dosage/oxygen scavenger injection that are prime concerns of operating teams that typically use probes and techniques that provide continuous rapid responses to changes in corrosion rate.

Inspection and monitoring technologies and techniques are described in a separate chapter in this book. In most cases use of inspection techniques (ultrasonics, gamma radiography, thermography, dye penetrant, magnetic particle and visual inspection) is a specialist area requiring employment of skilled technicians or appointment of contractors, particularly for applications such as intelligent pigging of pipelines (magnetic induction, ultrasonics) and down-hole/wireline inspections (callipers, ultrasonics).

On-site inspection methods, traditionally based on handheld devices such as ultrasonic testing (UT) equipment, were primarily used for postfabrication tests. The advent of digital techniques has improved the sensitivity, ease of data collection, and data handling capabilities which allows for improved display, data storage and trending. For example, computed/‘Filmless’ Radiography systems can now collect and analyze all radiographic data, completely replacing conventional films and aiding storage, and retrieval needs. Some inspection techniques have now evolved into permanently installed surveillance tools such as UT mats,<sup>52</sup> piezoelectric sensors embedded in electronic circuit ribbon<sup>53</sup> and alternative transducers such as the GE cMUT cell<sup>54</sup> a Si flat-panel capacitive ultrasonic micromachined transducer (cmut).

The relatively clear distinction, both technically and managerially, between the traditional fixed-time inspections and on-line surveillance/monitoring is therefore now more diffuse.

Corrosion monitoring techniques range from simple coupons, electrical resistance (ER) probes, electrochemical measurements in aqueous fluids, hydrogen permeation for sour systems, to more specialist methods such as the field signature method (FSM) and sand probes in oil/gas production. In some oil field systems, sand production/erosion probes may also be employed to identify specific problems.

In many flammable and hazardous areas, such as oil/gas production systems and chemical plant, the risk of failure/seizure of the probe assembly during insertion and retrieval has led to the requirement of a double block system. There is therefore an increasing emphasis on nonintrusive monitoring methods that can be operated from remote locations. These include spool pieces for ER and electrochemical measurements, externally attached ultrasonic devices mentioned above and FSM which uses a spool piece to assess changes in uniform corrosion damage, pitting, and erosion in lines.

The sensitivity and response from monitoring systems is crucial, particularly for high risk systems where, for example, a high inhibitor availability and efficiency is required and Figure 12 illustrates the relative corrosion rates and the response times from various probes based on linear polarization resistance measurements (LPRM), traditional ER, Hall-effect monitors and FSM.

Field data held in personal PCs is not readily accessible by the rest of an organization, neither is it

practical/effective to manage corrosion data systems from spread sheets. PC-based systems are increasingly employed, with either their own internal database or linked to the main asset database, but with the information readily available to other team members through an intranet link (transparent management approach). Input into electronic systems can be directly from hard wired monitoring instrumentation, from portable instrumentation/hand-held data loggers, and via keyboard entry as indicated in Figure 13. Data required for process control is usually retained in distributed control system (DCS) and supervisory control and data acquisition (SCADA) systems for a limited time period and therefore those data required as part of the corrosion management processing should be downloaded and retained in a separate database for correlation/trending.

Location of inspection/corrosion monitoring points need to be chosen carefully to ensure that they provide appropriate data for the specific application such as areas of high turbulence intensity, particularly where slugging-type flow or impingement of second phases occurs, or in areas of low flow or stagnation (dead legs) such as in the bottom of vessels and the 6 o'clock position in pipelines, in order to assess the aqueous phase/water dropout. Local variations of flow and temperature within processing equipment and pipework may have to be considered. In some cases, the highest/lowest temperature points that give rise to evaporation/condensation/concentration effects may be crucial. Such an assessment is typical of any corrosion risk evaluation where local variations can be significant.

**Figure 13** Inputs into a corrosion data system. Reproduced from John, D. G.; Attwood, P.; Rothwell, A. N. In *Corrosion'99*; NACE International: Houston, TX, 1999; Paper no. 249.<sup>55</sup>

The functions and roles of inspection and monitoring teams must be clearly defined and individual responsibilities for managing the systems, collecting and inputting field data, interpreting rate/correlating information and producing reports should be well understood. An overall management purpose is to devise strategies, tactics and systems that ensure that monitoring and inspection information contribute to safe and reliable operation irrespective of who obtains the field data. Those organizations that operate transparent data management systems are more likely to sustain the effectiveness of activities such as RBI, chemical treating, CP, the maintenance of coating systems, etc. that are so essential to successful asset management.

#### 4.30.4 Corrosion Management Systems

##### 4.30.4.1 Framework for Corrosion Management Systems

###### 4.30.4.1.1 The corrosion risk mitigation system

Previous subsections outlined typical tools employed in corrosion risk assessment, mitigation and field monitoring steps but these must be placed in an overall context involving teams, such as the planning and implementation team and the team for decision-making and taking corrective action steps. An overview of a typical corrosion risk mitigation approach is illustrated in [Figure 14](#), including feedback for control and the feed forward of information.

The inputs are corrosion concerns, life expectancy, life-cycle costs, project viability and SHE issues. The output is effective corrosion mitigation that is based on six distinct processing steps, including decision-making and actions:

1. Identification of individual corrosion team members, leaders/managers, and owners responsible for various procedures/processes/parts of the system.
2. Carrying out of the corrosion risk analysis.
3. Evaluation of the corrosion mitigation options.
4. Planning and implementation of the risk treatment process.
5. Development and maintenance of the required databases.
6. Regular use of informed decisions to instigate corrective actions.

Corrosion management requires that corrective actions be carried out as an outcome from the decision-making step. A structured approach with processes and procedures in place does not necessarily guarantee success without the key informed decision-making and action step. Team members must also undertake feedback from reviews, data monitoring, updating plans, and assessing secondary risks throughout the different project stages. Senior management/corrosion teams must allocate ownership of written corrosion risk assessment and mitigation procedures, planning and implementation processes and the decision-making step. Other inputs, for example, include the development and application of performance reviews and KPIs, and ensuring that management of change procedures

**Figure 14** Outline of a corrosion risk mitigation system.

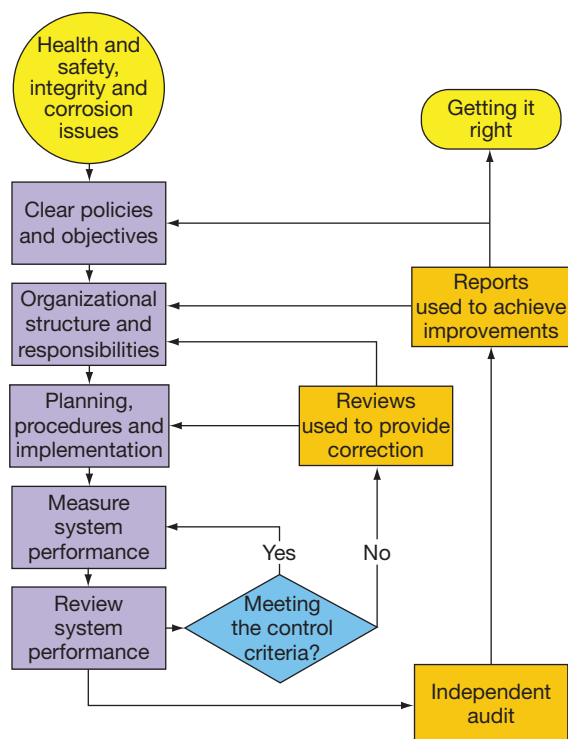

and monitoring of action effectiveness are in place. Some of these, such as KPIs, are also management control methods as will be described below in connection with [Figure 15](#).

#### 4.30.4.1.2 Corrosion management systems

Only in the past 10 years have formal corrosion management systems received attention in the literature, in contrast to voluminous publications on corrosion risk mitigation tactics. Formal systems for integrity management, including the use of competent persons, have been employed for over 50 years in industries where catastrophic failure prevention is crucial and SHE issues affect an organization's image. From a financial perspective, the prevention of engineering failures that affect up-time, throughput and process efficiency, and ensuring that corrosion risk mitigation in new projects and operations is cost effective, requires a responsive corrosion management system

that integrates seamlessly into an organization's design and asset management systems. A corrosion management system should have many of the steps contained within a corrosion risk mitigation system but must also have feedback, reviews/audits and performance indicators to ensure that it operates effectively and is compatible with other management systems within the organization.

The original basis for the approach given in [Figure 15](#) was the UK HSE *Successful Health and Safety Management* model.<sup>10</sup> The input and feedback loops were added by the author during the mid 1990s for industry-based corrosion training courses and was first reported as a generic corrosion management model in 1998.<sup>56</sup> It was developed further in 1999<sup>4,8</sup> in connection with continuing concerns by the UK HSE on hydrocarbon emissions from UK North Sea offshore processing facilities. A primary aim was to develop a template based on the UK regulatory authority's

**Figure 15** Basic management steps and feedback loops needed for control.<sup>4,8</sup>

approach to safety management and adoption of a common assessment of the corrosion management systems already in place.

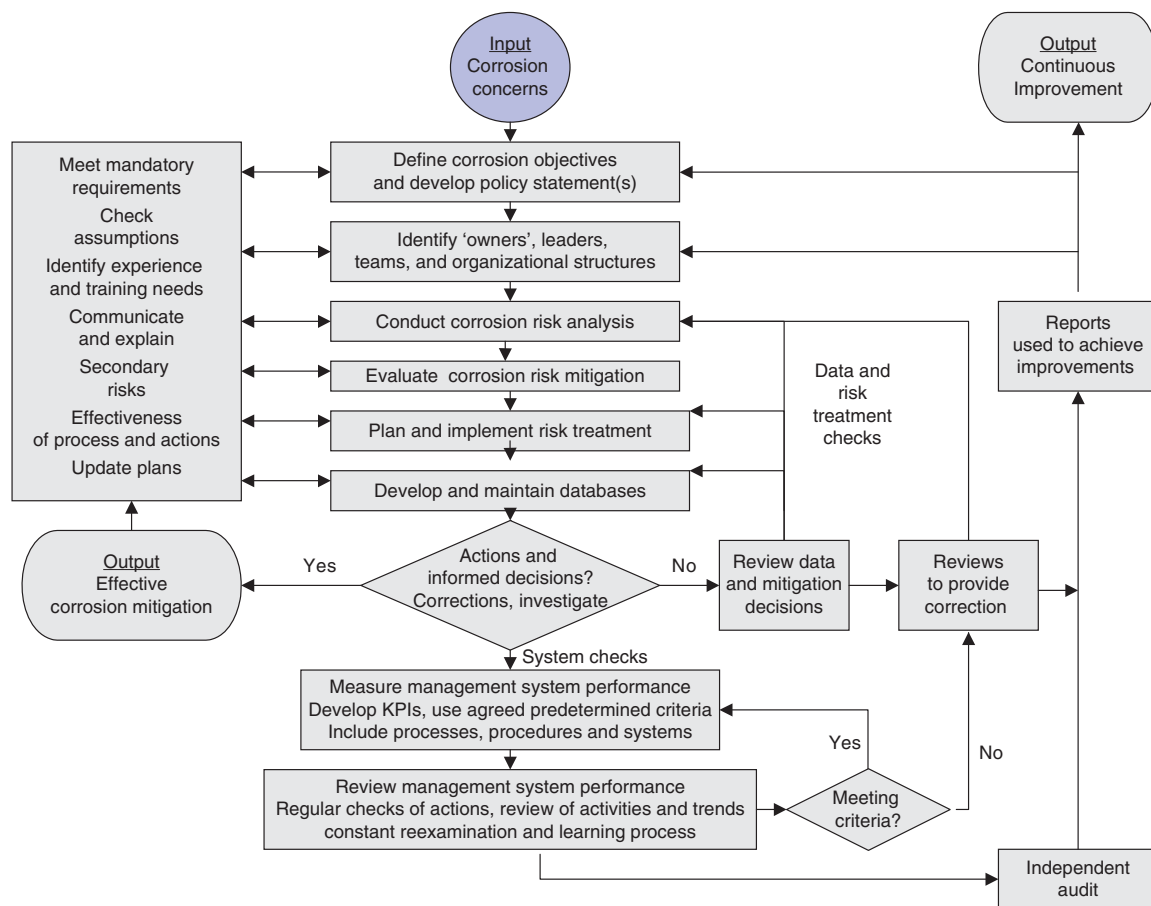

The concern over hydrocarbon releases but also external corrosion damage of structures continued in *Guidance for Corrosion Management in Oil and Gas Production and Processing* published in 2008<sup>48</sup> and was first outlined in a workshop<sup>57</sup> in Aberdeen. The guidance focuses on the impact of internal and external corrosion, on integrity issues in existing facilities and is complemented by a *Corrosion Threats Handbook*,<sup>47</sup> the information presented is also instructive to designers of new facilities. The main text describes what would be appropriate for an oil/gas processing corrosion management system. The management system flow sheet differs slightly from **Figure 15** in that the corrosion risk assessment/planning process and the implementation/analysis process are separated. Information on tasks and details and photographs of damage inspection are presented. Annex A provides *Guidance to Normative Requirements and Examples of Good Practice*, Annex B outlines the *Top Corrosion Threats and Corrosion Mitigation Methods* and Annex C provides a useful eight-page *Checklist for Assessment of Corrosion Management*. It is significant that this document

considers that the corrosion management system requirements outlined should be considered normative for UK operators.

An illustration of the use of the corrosion management system to address external corrosion/coating issues<sup>58</sup> was presented in the Aberdeen workshop<sup>57</sup> where a risk-based assessment method was developed to enable work prioritization on structures, piping, handrails, walkways and gratings. Coatings condition/inspection was recorded in databases with the performance monitored on a visible KPI reporting system based on the ISO paint standard reference scale for coating breakdown.<sup>59</sup> Re5 and Re7, equating to 8% and more than 35% coating breakdown respectively, were judged to be the intervention levels for piping and structures, respectively, for the study. This then formed the basis for planning the work scope which included the ability to determine a cost effective long-term painting strategy allowing for scenario analysis and cost effective management. The importance of external corrosion mitigation/integrity of walkways from the regulator's viewpoint can be seen from their external corrosion project<sup>60</sup> that aims to reduce risks by a combination of improvements to both the physical condition of installations and the management systems in place.

A more general approach for corrosion management systems in a range of applications and project stages but based on the risk management approach described previously<sup>31</sup> as shown in **Figure 16**. Major factors for any corrosion management system are a series of logical steps and an ability to review and audit those steps. The flow sheet in **Figure 16** indicates typical processing steps required in a system that incorporates both a risk-based mitigation process and control of the management process. The inputs are corrosion concerns in the context of the project and SHE issues, etc. The main processing steps are risk-based and auditable with effective corrosion mitigation and continuous improvement as the outputs of the management system.

**Figure 16** should be read in conjunction with the mitigation detail provided previously in **Figure 14** and the outline of the system review and audit shown in **Figure 15**. The inclusion of the concept of continuous improvement is a quality management system criterion output, as discussed previously, whilst the crucial step in any management process must be informed decision-making, based on reliable data. Procedures and protocols form the basis of a management system but without responsible and informed decision making the overall process will fail. Any management

**Figure 16** Requirements of a corrosion management system.

system has also to be regularly reviewed to ensure that the various steps continue to meet predetermined criteria as addressed by the development and use of performance standards such as KPIs.

In practice, many corrosion management systems will combine two or more steps/tasks/actions in some processing steps but the overriding requirement is to ensure that the different tasks and associated overall management actions are completed. In many ways [Figures 15 and 16](#) provide a template or idealized corrosion management system, without attempting to prescribe exact arrangements within established organizational systems. For example, a basic documentation and data control system will be needed at the start of a project but will not appear in its fully operational state until later. Details of the key steps for both mitigation and management are given below:

1. *Aims/objectives/policies.* An initial step in developing a corrosion management system is to define the aims and objectives of the corrosion input to a

project. These then form the basis of the corrosion policy, in principle, a permanent directive with authority from senior site management. The policy specifies overall/longer term objectives such as lowest life cycle costs during design, no leaks or emissions during the operational phase or with life enhancement meeting the required life, etc. The policy may incorporate elements of an organization's safety or environmental policy or even simple day-to-day guidance, such as that general corrosion rates should be less than 10 mpy. Guidance on the series of steps was outlined in the corrosion policy definition given in the chapter introduction. This includes establishment of organizational structures with defined responsibilities, reporting routes, practices, procedures, processes, and resources. It also requires the demonstration of responsibility and accountability for corrosion performance, managing risks, decreasing costs, controlling compliance, and motivating personnel.

2. *Individuals/teams/organizations.* Identification of individuals and teams with ownership of corrosion management processes also helps to define roles, responsibilities and accountabilities of managers, staff and contracted bodies concerned with corrosion issues. Appointment of corrosion team members with appropriate skills, an experienced team leader and an asset/project manager would be typical with the team comprised of representatives from the design team, engineering, inspection, production/operations, coatings/chemistry/biological laboratories, specialist contractors/consultants and even vendors/suppliers. Project boundaries with related/associated activities such as asset integrity (inspection teams), maintenance (engineering department teams) and production (process engineering teams) must be defined. Technical competence of personnel is normally a given but for nonspecialists/managers appropriate training may be required. Communication routes should be clearly identified and cooperation between team members and other groups encouraged ensuring that corrosion implications for other areas of activity are understood. The use of transparent data bases/trend information is helpful and often crucial.
3. *Corrosion risk evaluations and assessment of mitigation options.* These are fundamental steps conducted throughout the project life as conditions and facility operational requirements/procedures change. At some stages, such as design or plant upgrades/life extension, these activities form the largest single part of any corrosion management process and can have the largest impact on life-cycle costs and reliability. Issues arising from consideration of secondary risks or failure of a specific corrosion mitigation procedure must also be addressed. The basis of the designs/decisions must be clearly documented with materials/process limitations highlighted in the corrosion/operating manual for each unit. This should link through to management-of-change documentation, etc. The development of corrosion risk mitigation procedures includes the development and the methodology for documentation the implementation of various corrosion risk assessments and corrosion mitigation measures.
4. *Corrosion risk treatment planning and implementation.* These are vital to ensure that strategic, tactical, and operational/day-to-day activities designed to mitigate corrosion are employed effectively. Strategic activities address longer term issues such as best practices to ensure optimal life-cycle costs, SHE/mandatory requirements, corporate corrosion practice/integrity requirements and business concerns including the development of condition-based maintenance/equipment reliability/uptime needs. Such issues should have been considered as part of corrosion risk/mitigation analyses with the outcome requirements specified to provide for detailed plans to be developed. Planning involves the production of methods and/or procedures for all activities including specification/procurement of materials, testing, fabrication/welding, coatings/CP equipment applications, corrosion monitoring/inspection instrumentation, field data collection/analysis, required databases and their population, specification of reporting by appropriate routes and development of corrective action procedures to be carried out when necessary. Corrosion management plans should be formally recorded in the system documentation as part of a facility design and construction record, including consideration of facility start-up, operating, emergency/shutdown procedures where conditions impact on corrosion mitigation. Planning also includes assessment/development of chemical treating, inspection, and maintenance procedures. In many cases, these in-house company standards/protocols are typically based on international standards such as ISO, NACE, API, DnV, etc.
5. *Database development and maintenance.* Suitable databases for storage of system documentation, facility design/as-constructed diagrams, commissioning information and field data during operation/inspection/maintenance is a given. Specification, development, and maintenance of databases must be carried out in conjunction with stakeholders who will operate the system. It is not recommended that a design contractor/central authority specifies the system without adequate consultation. Consideration must be given to how previous experience/design/construction data is transferred through to the operational phase database. Examples of what may be required include: changes from the basis of design, testing requirements, modifications, that is, how will the incorporation of likely changes noted as part of the basis of design be built into the operating and maintenance/inspection plans? Also postfabrication inspection data provides the initial field data point for trending as in RBI and should be linked with specific locations on P&I/line/isometric diagrams. The means by which field data such as

visual inspections/coating surveys, hand-held/permanently wired instrumentation, DCS/SCADA downloads is to be collected, is analyzed and used for trending/correlations must be agreed and specified.

6. *Informed decisions and actions.* These are key processes; many management systems fail because of a lack of a clear decision-making step even though adequate protocols and procedures are in place. Corrective actions are an outcome from the decision-making step and these include investigative studies, the issuing and following-up of warnings or even instigating shutdown actions when required. Operational/day-to-day actions include rescheduling of inspections, change of chemical treating and predictive maintenance work that involve other teams. Any recommendations made must either be followed up or rejected in a positive manner due to other factors but not by default.
7. *Performance measurement of the management system.* Regular checks on the operating system should be conducted against agreed-upon predetermined criteria – the performance standards or KPIs. Responsibility for overseeing this process should lie with suitably competent individuals who are, ideally, appropriately free of production pressures. Performance measurement covers all aspects of the processes, procedures, and management systems using different levels of measurement at appropriate frequencies. Some may require immediate review/measurement on completion of a task. Measurement systems may be either proactive (to ensure agreed criteria are being met or identification of an inadequate system) or reactive (a postfailure activity to evaluate repair incidents or near misses and identify improvements).
8. *Regular reviews.* These are normal in-house checks of overall corrosion management system performance. They ensure that management procedures and processes are consistent with any changing business plans, changing production requirements and changing legislation. The aim is to improve performance and reduce incidents, improving conformance to schedules and improving procedures. It is the constant reexamination and incorporation of lessons learned that lead to continuous improvement of the corrosion management system.
9. *Periodic audits.* Management and monitoring system audits provide evidence that the corrosion management system is efficient, effective and reliable, and that processes and procedures are being implemented in accordance with agreed upon procedures. Regulations typically require owners

to ensure that adequate arrangements are established for audit report-making.

**Figure 16** was developed from a risk-based approach for corrosion mitigation that also provides a structured framework for control of the management system by use of reviews/audits/performance indicators. It is able to integrate statutory SHE goals and delivery of cost benefits to a project. In practice, contributory factors such as identification of training needs, management of change and end of life strategies will also have to be addressed where required. Delivery of a working system will depend on the use of performance indicators for both the management system, **Figure 16**, and the mitigation system, **Figure 14**.

#### 4.30.4.2 Setting Performance Measures

Use of performance measurement/KPIs is a normal practice in most quality and safety systems. For example, the UK pressure system regulations require asset owners to record/inform the regulatory authorities of any delay to a scheduled inspection. The delay may be justified in order to either fit in with a scheduled maintenance shutdown or due to other valid operational reasons. However, a second, further delay beyond the next scheduled inspection is not permitted, the aim being to ensure that the plant is not operated in an unsafe condition; an illustrative proactive use of a KPI. A significant record of inspection delays is likely to be symptomatic of significant management problems.

Typical objectives of performance measurement/KPIs for corrosion management are:

1. Ensure that corporate corrosion objectives are met with respect to SHE and financial issues, usually by reactive/lagging indicators.
2. Ensure that strategic/tactical/operational strategies are implemented effectively by checking the success of corrosion management activities, often by checking on the success of plans by proactive/leading indicators.

These might be translated into specific indicators for various project stages and organizational levels as follows:

1. *Corporate level*
  - Provide written policy statements.
2. *Strategic level* (design/proponent/asset manager/owner)
  - Ensure that corporate/SHE/local legislative/long term objectives are addressed.

- Ensure that corrosion rates provide the agreed upon equipment life and that cost effective corrosion mitigation is employed.
  - Ensure that individuals have delegated responsibility/ownership of corrosion issues and identify who is accountable for various components of the corrosion mitigation program.
  - Ensure that corrosion risk assessments and sensitivity studies are conducted as a regular feature of project/design/inspection/operations/maintenance activities.
  - Ensure that decision makers are suitably trained/competent/responsible to action necessary changes/modifications/issue work instructions for the improvement of corrosion mitigation processes.
  - Ensure that various aspects of the program remain effective with stated time frames when they will be updated/reviewed/audited and that management-of-change procedures are in place.
  - Ensure that the performance indicators are acceptable/measurable/achievable/realistic.
3. *Tactical level* (design/proponent/asset manager/owner, plus supervisors from design, engineering, production, maintenance, inspection, corrosion).
- Ensure that a corrosion team leader/team members are allocated/named as part of the design/construction/O & M/project teams.
  - Ensure agreed-upon codes/standards/in-house guidance/procedures/work practices are authorized/reviewed/audited at set intervals and placed in a central quality controlled documentation database.
  - Ensure that corrosion mitigation methods employed are appropriate/cost effective/suitably managed/monitored/subject to regular review/audit.
  - Ensure that annual review of corrosion/inspection/chemical treating/CP/coating systems are carried out.
  - Ensure that audit of corrosion/inspection/chemical treating/CP/coating systems are carried out every 2–5 years.
  - Carry out an internal audit of the corrosion management system (6 months after implementation and thereafter on an annual basis).
4. *Operational/corrosion team level* (Responsibilities reside with specific individuals depending on the size of the operation and organizational arrangements; these could include managers, supervisors, corrosion team members).
- Specify and cost materials (\$ per mm) as part of life-cycle studies including any testing required.
  - Ensure that cost effective corrosion mitigation is employed such that corrosion rates are consistent with the corrosion allowance/required integrity/agreed upon life of equipment.
  - Optimize chemical treatments.
  - Report any corrosion related failures identified during routine inspections or data acquisition.
  - Undertake urgent field activities within 24 h of the request.
  - Enter all planned field data into the appropriate database within 1 week of taking the measurements for low and medium risk items.
  - Collect corrosion monitoring data and download data to asset management database within 1 week of due date.
  - Issue a written report about out-of-compliance findings within an agreed-upon time period of taking measurements.
5. *Corrosion team leader*
- Review records to assess conformance and report out of compliance when necessary.
  - Track specific procedures and processes to ensure compliance including competency of responsible individuals, departments, and organizations and correct implementation, reporting and reaction.
  - Check if appropriate investigations were undertaken in accordance with procedures.
  - Check if the investigations were effective and that necessary changes to procedures/processes are developed to prevent recurrence.
  - Have the changes implemented/incorporated into procedures/processes.
  - Review the corrosion related documentation.
- Examples of measurement of corrosion management performance can be found in oil/gas production,<sup>8,48</sup> chemical treatment of systems,<sup>61</sup> coatings maintenance<sup>58</sup> and management of CP systems where much of the practical requirements are covered in the EN on CP and Cathodic Protection Measurements.<sup>62</sup> For example, following successful commissioning of a CP system and establishment of a steady state CP level, the following checks would be typical for the basis of development of KPIs and data review by an experienced CP specialist:
1. On a monthly basis check for satisfactory operation of transformer-rectifier and record output voltage and current.

2. On a six-monthly basis record polarized pipe-to-soil potentials at each test station, especially those located furthest from the CP drain point. Visually check all test facilities and transformer-rectifiers for serviceability and damage and carry out maintenance and repairs as necessary.
3. On a 12-monthly basis repeat the six-monthly tests and also test for possible stray current interference effects where other facilities are located close by.
4. At intervals of 5–8 years carry out a close interval potential survey (CIPS) and a direct current voltage gradient (DCVG) survey to assess changes in performance of both CP and coating in order to accurately determine the status of the CP on the entire length of the pipeline.

Recommendations/conclusions by the specialist should be acted upon without unreasonable delay to ensure the continued satisfactory CP of the pipeline. Many organizations fail to respond to reports submitted by their own teams and specialist contractors because of a lack of appropriate KPIs used to ensure that the required actions are carried out as scheduled and appropriate decisions are made when required.

#### 4.30.4.3 Data Management Systems

Documentation, both paper-based and/or electronic, form part of any management or quality management system. The choice will depend on the size of the project/operation. In many facilities such as refineries, oil/gas production fields and chemical plants the complexity of the various plant items/infrastructure plus the various corrosive environments can make the recording, trending, and correlation of data a difficult task. A number of PC-based software systems are commercially available that focus on specific aspects such as the recording of inspection or CP data. There are many common features<sup>53</sup> amongst the various integrated asset management systems employed to manage corrosion/inspection/CP systems/chemical treating. To be fully effective for corrosion management they should not only link to the maintenance/production systems but also output control instructions for activities such as planning, work control, stock control, materials handling, project management, procurement, contracts and finance. The requirements include:

1. *An asset register* – which is user configurable, holds design information, line diagrams and as built drawings, etc., that is, usually an electronic system that accurately reflects the physical facilities. These are set up in a logical/hierarchical manner

to identify individual equipment (Tags) that is, physical items that perform a function, such as vessels, units, etc., some of which may be interchangeable for maintenance, their components or segments for example, pipe work/the position/measurement locations. A typical asset register/facility list may include: plant code, area (plants, storage facilities and utilities), station (downhole, flowlines/manifolds, sub-sea facilities, gas compression systems and pipelines), position (vessel internals and equipment component) and line list (pipework database).

2. *A documentation system* that contains supplementary information and data on the above such as environmental conditions, pipe classification and constructional materials. These are usually held in separate listings on user-configurable records in a standardized format and include additional information and data such as that which has been scanned electronically from photographs, images and hand-drawn sketches, CAD drawings, and text files.
3. *Data collection input and interfaces* – these include keyboard entry, an ability to collect selected process data and download data from hand-held, portable or hard-wired instrumentation, plus the ability to operate on standard PCs/servers and especially have compatibility with other IT platforms.
4. *Data analysis capability* – ability to retrieve/trend data, cross correlate/determine equipment condition/process history/identify common corrosion circuits/predict future life. Data-trend displays, with alert/warning indicators, are needed to determine when deterioration is at a level necessary for corrective/maintenance action.
5. *Planning/work control* – ability to schedule activities and check on progress.
6. *Reporting* – identify safe/unsafe conditions (alert and alarm warnings), produce audit trails, generate recommendations and create action lists.
7. *Functionality enhancement* – capable of extension to encompass/interface with maintenance systems/materials procurement systems/contract/project control systems/finance systems/executive information systems.

Corrosion management and inspection management databases need a functionality that combines data storage from monitoring and inspection records, analysis of trends and predictions of remaining life, evaluation of corrosion circuits (process streams with similar corrosion from analysis of process stream changes) and generation of management reports for

decision making. The ability to compare data from various sources to produce reports/conduct financial evaluations/just-in-time inhibitor deliveries, etc. is a key requirement of a corrosion management system. For example, although field data is a key input into the management of operational plant and facilities, the acquisition and disposition of field information does not necessarily mean that adequate knowledge of equipment/plant condition is available or that the performance of the asset/facility process is provided in a lucid or easily understood manner. The system should bring the corrosion language in line with that of asset managers/the boardroom.

Effective corrosion management requires, for example, that the inspection frequency and information must be combined with online data from corrosion monitoring, which is used to control chemical treatments, such as corrosion inhibitor/biocide dosage or oxygen scavenger injection, plus the retrieval of appropriate process data such as flow rates, temperatures, and fluid compositions from SCADA systems. This flexibility of software is typically found in an IT benchmark product such as *Amulet*<sup>63</sup> which is used in a wide range of industries ranging from water companies, supermarkets, waste disposal, mobile phone stations for maintenance/operational control of various activities; it has also been employed for the management of corrosion data from various offshore and onshore production facilities including refining/oil field treating chemicals/management of corrosion monitoring/inspection/CP. Inputs are from probes, laboratory analysis, third party/historical/archive databases, as described previously in **Figure 13** with outputs including alarms/anomalies, mitigation schedules, reports leading to key performance checks, actions for inspection/maintenance.

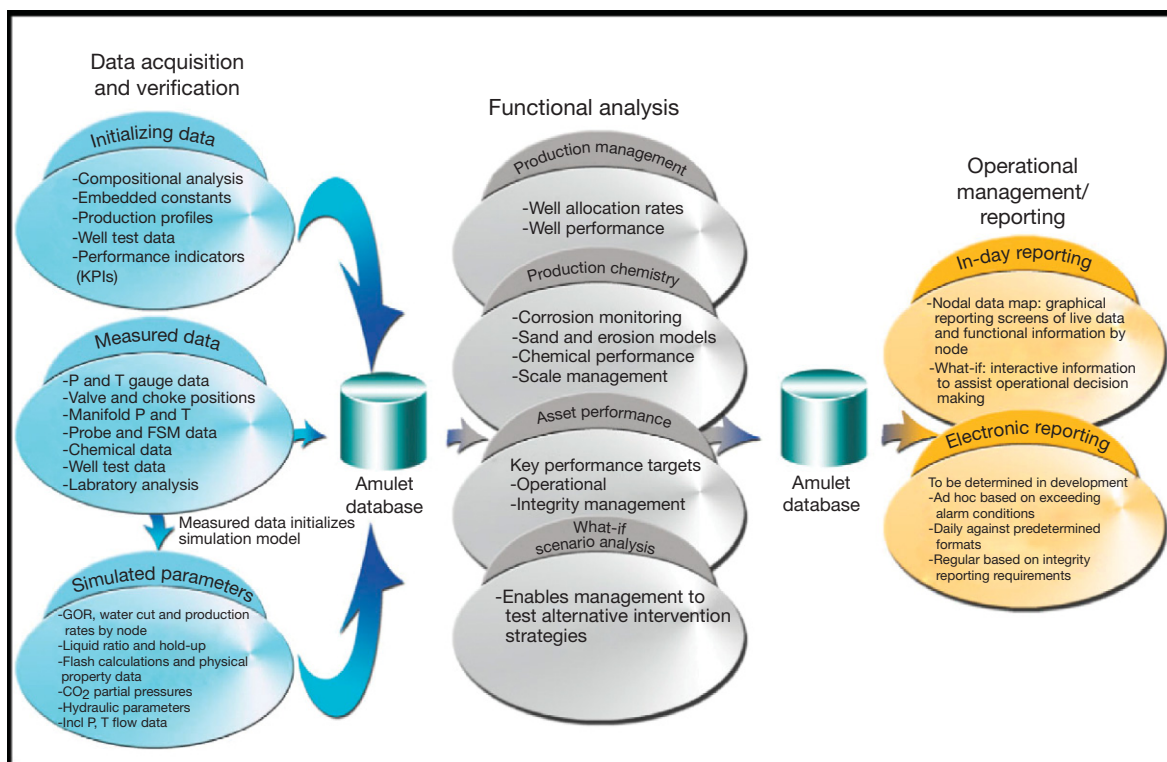

Typical reports to the corrosion team/decision-makers from a data management system would include: wall thickness calculations, remaining life analysis and prediction, inhibitor treatment and usage, corrosion coupon and retrieval reports, advice on type, location, frequency of corrosion monitoring, corrosion prediction, pipeline inspection, periodic status reporting, deviation reporting, traceable records of installation corrosion history, CP data-trending, CP on/off test reports, anomalies for CP test posts, corrosion damage/failure analysis, defects categorization, leakage and spillage reports, downhole log reports, and changes to operations/maintenance/inspection activities and scheduling. **Figure 17** illustrates the typical data flow and outputs that form the basic reporting to the corrosion management system/team.

The type of management questions asked of such systems<sup>55</sup> are about the:

1. Distribution of corrosion rate in various parts of the system  $<0.05 \text{ mm year}^{-1}$  ( $<2 \text{ mpy}$ ),  $0.05\text{--}0.25 \text{ mm year}^{-1}$  ( $2\text{--}10 \text{ mpy}$ ),  $>0.25 \text{ mm year}^{-1}$  ( $>10 \text{ mpy}$ ).
2. Present distribution of remaining life, Items requiring replacement in:  $<1.5$  years,  $1.5\text{--}3$  years,  $3\text{--}10$  years,  $>10$  years.
3. Cost of the current corrosion control program.
4. Costs of chemical treatment.
5. Costs of CP.
6. Repair/maintenance/replacement costs.
7. Downtime (lost production) costs.
8. Inspection/monitoring costs.
9. Business drivers/criteria which have been met.
10. Average corrosion rates.
11. Allowable outage (offline) time.

**Figure 18** shows data from oil field chemical treating that correlates chemical usage with production rates to provide financial information on the treating program. This illustrates the point that data management is not just providing trends of corrosion rate, metal loss, chemical use, etc. for reports but that useful management information is abstracted by suitable correlations/analysis to enable appropriate decisions to be made regarding operational, integrity and strategic/tactical issues. Further information on monitoring and data handling, including case studies can be found in *The Corrosion Monitoring Handbook*.<sup>64</sup>

The above section has highlighted how systems for the control of project documentation, including standards, guidance, specifications, design, construction, and operating/maintenance procedures and protocols typically form part of a quality assurance system and provide a key input to any corrosion management process. Equally important is the functionality of the data management system used to store field data that has then to be converted into information for the decision makers. Both form discernable parts of the corrosion management system, as do the organizational arrangements and reporting routes. All have to be subject to regular reviews and audits to ensure that they, together with the various project teams, deliver effective corrosion mitigation. Successful data management systems are those that are used on an everyday basis as a live system, often through a web based/transparency methodology, to actively control all aspects of the mitigation processes including costs and actions. Some are specified to indicate on a traffic light basis the corrosion conditions of

**Figure 17** Schematic of data management. Courtesy of A. N. Rothwell. Reproduced from Amulet, C<sup>3</sup> Ltd., Dingwall Business Park, Dingwall, UK.

**Figure 18** Correlation of cost of chemical treating with production. Courtesy of A. N. Rothwell. Reproduced from Amulet, C<sup>3</sup> Ltd., Dingwall Business Park, Dingwall, UK.

units throughout the asset. In practice, many systems provide regular reports but essentially prepare data for storage/long-term burial rather than playing a key part in the decision process.

#### 4.30.5 Conclusions

There are many ways to organize and operate successful corrosion management systems, each of which is asset specific and dependent on factors such as design, the life-cycle stage, process conditions, operational history and organizational culture. Key issues from the project/asset manager perspective are corrosion risks that threaten structural integrity, economic viability and SHE performance. Most organizations rely on nonspecialist managers, designers and plant engineers to manage the facility corrosion specification, operational aspects and day-to-day activities required to mitigate corrosion whilst specialist corrosion/materials engineers are normally employed in an advisory capacity only. This is a pragmatic and appropriate use of a limited resource provided that corrosion issues do not become every employee's concern but no person's responsibility.

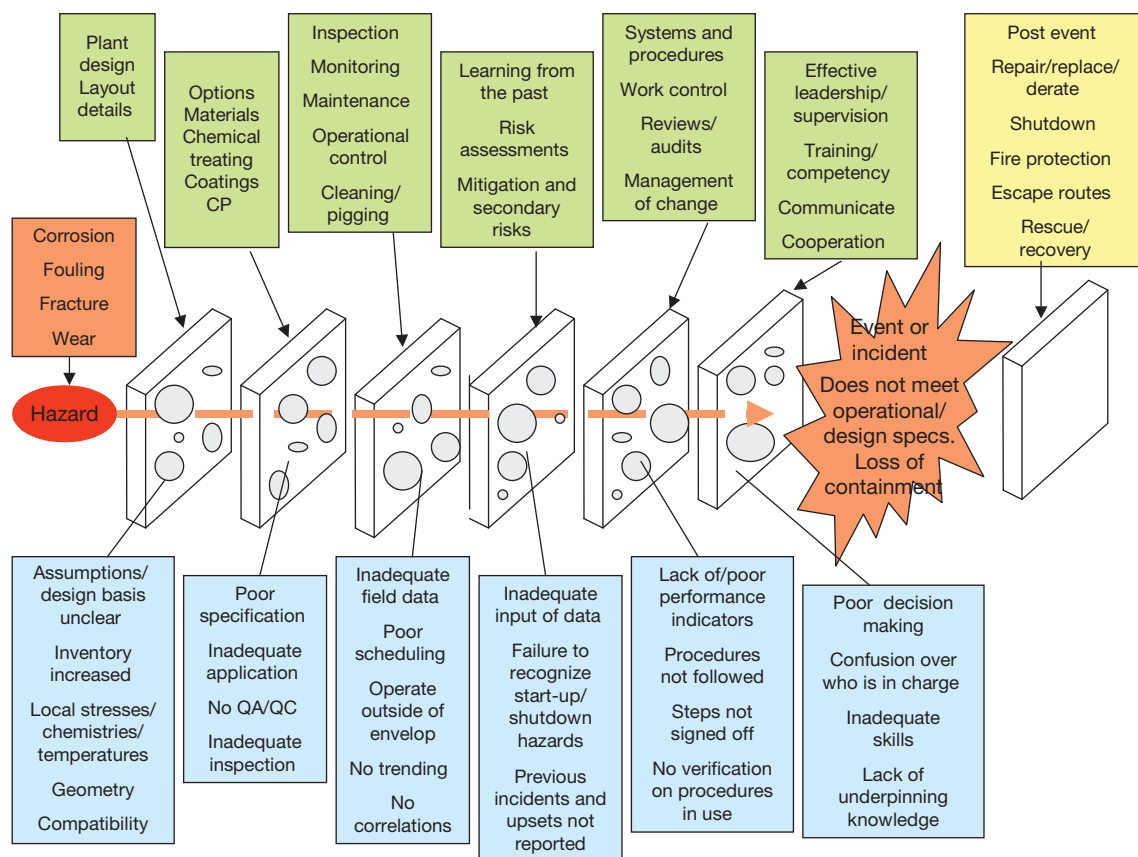

A primary aim should be to make corrosion risk management an integral part of both good management practice and the training/educational process within organizations. All risk management processes comprise a series of iterative steps that promote

continuous improvement in decision-making. Effective corrosion management depends on the experience and judgment of corrosion team members/leaders to provide guidance to design, construction and asset managers but such teams may also have to learn new management skills to be more effective. Incidents, failures and poor equipment performance will occur if reliance is placed solely on a routine of following steps outlined in procedures, guidelines and standards. Individuals must be aware of competence limitations and recognize when to call on more experienced members of staff/third parties. Senior management support is also needed to define clear strategies and corrosion policies that are promoted by the adoption of workable corrosion management systems using correct technological tools operated by trained people who have the motivation and commitment with adequate supervision.

Management system failings and human errors pose as big a risk to corrosion mitigation as do physical and chemical hazards. Serious corrosion related incidents occasionally make the front page such as

the 1988 Aloha Airlines loss of a cabin roof during flight due to adhesive failure, crevice corrosion and fatigue cracks,<sup>65</sup> the Humberside refinery fire<sup>5</sup> referred to previously and the recent Alaska pipeline leak due to a lack of cleaning and inspection by pigging.<sup>66</sup> These are the tip of an iceberg and, with hindsight, preventable, but they beg the question whether lessons are learned from the minor leakages, poor equipment performance and shorter-than-expected lives that are an everyday occurrence in industry at large.

Catastrophic incidents from other engineering sectors, particularly investigations of process plant failure, provide insights how established process/safety engineering methods could deliver continuous improvement of corrosion mitigation practice. For example, control of safety hazards to prevent incidents can be visualized as a series of barriers. Some are hard/physical, others are soft/procedures/systems, but each will have weaknesses. This 'Swiss cheese' hazard management model,<sup>67</sup> depicted in Figure 19, illustrates that as long as the holes in the

**Figure 19** Example of a degradation hazard management concept.

various protective barriers/layers do not align then a hazard can be controlled but that a series of human errors/unmanaged circumstances can give rise to porosity in the hazard control barriers resulting in incidents and catastrophic accidents. This hazard management model was used recently to analyze the March 2005 Texas City refinery incident.<sup>68</sup> The study emphasized the extent to which hazard prevention depends on three layers of protection:

1. *Plant* – engineering hardware, control systems, and layouts to eliminate, control and mitigate potential hazards to people, and improve productivity.
2. *Processes* – management systems to identify, control and mitigate risks, and drive continuous operational improvement.
3. *People* – capability of our people in terms of leadership skills, relevant knowledge and experience, and the organizational culture they create in layers of protection, ‘hard barriers’ are more reliable than ‘soft barriers,’ but all rely on people.

A list of typical problem areas at the refinery included:

1. Incidents and upsets not reported.
2. Hierarchy of control not applied.
3. Previous start-up review not performed.
4. Procedural compliance not checked.
5. No interventions.
6. Inadequate KPIs.
7. Lack of underpinning knowledge.
8. Failure to follow procedures.
9. Confusion over who was in charge.
10. No verification on procedures in use.
11. Procedures not followed.
12. Steps not signed off.
13. Use of local practices.

Learning from the Texas City incident would be relevant to most corrosion related incidents where equipment fails to meet design/operational requirements due to deficiencies in the inputs from corrosion risk mitigation tools, systems and teams. As indicated in **Figure 19**, hazards to performance/structural integrity arise from a combination of one or more of the generic degradation processes, corrosion, fouling, fracture and wear. The hard barriers for mitigation of corrosion related hazards that include fit-for-purpose materials, coatings, chemical treatment, CP, etc. are more physical and robust than the soft barriers that include generic management systems for control of mitigation processes. The robustness of all barriers depends on effective

functioning of individuals and teams who must respond to continuing changes. Holes in various barriers introduced by individual/team action or inaction are indicated in the lower boxes.

Corrosion technology is not new; corrosion mechanisms are understood and documentation/standards/knowledge on corrosion mitigation tactics are widely known and available. The difficult part is in translating this corrosion background information into reliable solutions for the real world. Important aspects are not only technical solutions but also involvement/acceptance of key personnel, particularly in organizations where management of change involves different ways of doing things, as demonstrated in a study of a long-term problem with hot potassium carbonate acid gas removal plants.<sup>69</sup> Organizational aspects were identified as critical and the *Six Sigma* methodology,<sup>70,71</sup> traditionally employed to solve problems in manufacturing and continuous process industries, was used as a tool. The principle is that improvements occur when people doing the job are involved, guided by an individual experienced in the implementation methodology. Mature organizations with workforces that are highly experienced and knowledgeable may be less adaptable to change as, for example, is sometimes found when RBI is proposed/introduced. In the above site corrosion study, a team approach encompassing integrity, process and process control engineers and chemists provides a broader input to define the problem, identify the likely root cause and then deliver the required change by enabling the management decision to release the funds necessary for improvement.

Delivery of services such as corrosion mitigation in an era of increasing demand, in more difficult environments, and often with squeezed budgets, requires development of strategic models that may well include input from both in-house and third-party specialists. What counts is the provision of improved quality and value rather than whether the service provider is in-house or a contractor. Asset-centered organizations based on multidisciplinary teams tasked with improvement of the asset management processes of optimizing costs, risks and performance, are increasingly replacing traditional activity-centered organizations based on functions such as design/engineering, production/operations, maintenance and materials/purchasing with individual budgets. The new focus is on inputs with responsibility for investment/expenditure and outputs of performance/accountability. The asset manager and team have budget decision-making responsibility for

resources and services. The client ‘assets’ provide funds for technology specialists, designers, information technology, human resources, SHE and finance, obtained from both in-house, central, shared sources and external providers. The challenge for an operating company/asset is to choose those services required to achieve defined objectives that realize longer term savings/benefits.

Such developments in asset management cannot be ignored in the delivery of corrosion management services and may even continue to drive the changes instigated in the 1990s by SHE issues. Corrosion management, defined previously in [Section 4.30.1](#), is also part of asset management, which is in turn now defined<sup>72</sup> as “Systematic and coordinated activities and practices through which an organization optimally and sustainably manages its physical assets and their associated performance, risks and expenditures over their life cycles for the purpose of achieving its organizational plan.” An organizational strategic plan, based on stakeholder aims/expectations and legal requirements, is translated into local asset business goals with intentions converted into actions as depicted in [Figure 20](#).

Best practices and development of risk-based methods for management of physical assets formed the basis of MACRO, a multiindustry collaboration project, which was a UK government supported joint venture and a European ‘Eureka’ Project, EU1488.<sup>73</sup> The aim was to promote a change in approach that incorporates guidelines, education and decision-support tools

(Asset Performance Tools (APTs))<sup>74</sup> that comprise a set of methods to quantify and optimize over 40 different types of asset management decisions in target areas such as asset life-cycle costing, inspection and condition monitoring, maintenance optimization, work grouping and shutdown strategy. An outline is provided in ‘*Risk-based Decision-making in Maintenance, Inspection, Spares and Asset Renewal*’ by John Woodhouse.<sup>75</sup> This highlights some of the limitations of tactical/bottom-up/individual task tools such as FMECA, RBI, reliability centered maintenance (RCM), Six Sigma, and TQM that focus on one risk at a time, whereas the APT suite is designed to address multiple interacting risks and performance.

For example, APT-Inspection can help in deciding optimum asset inspection intervals as illustrated by Smith<sup>76</sup> who compared the total impact on items comprising a continuous chemical processing unit by optimizing inspection costs, outside limit risks and operational failure risks. FMECA was used to determine maintenance strategy and RBI showed most items had an optimal 4-year inspection/shutdown frequency, but some a 3-year and, a particular HCl stripper, a 2-year frequency. Changing some materials of construction for the stripper and pipework and also assessing a small column containing sacrificial iron packing by APT-Maintenance for loss of efficiency showed that an in-line spare column was a cost effective approach. Although there were some relatively small costs associated with the implementation,

**Figure 20** Asset Management System. Adapted from BS PAS 55.

the benefits amounted to a NPV of £2.5 million over 12 years.

The need to meet increasingly challenging SHE and financial demands will need a cultural shift in corrosion thinking within both industrial organizations and educational establishments that will require a wider appreciation of risk-based approaches and exposure to mainstream engineering concepts found within safety management, asset management, project/process management and maintenance management. A shift in the management model for corrosion services based on different approaches to the management of corrosion risk mitigation requires new standards to be set if the design/planning and operational delivery phases are to improve. This will include increased information sharing, system transparency and merging of services, including partnerships with specific contractors in order to benefit from shared experiences and additional/different resources. Cross fertilization of approaches, tools and procedures is occurring as in the cases of functionality analysis, criticality assessments and RBI in the petrochemical industries, total productive maintenance in the manufacturing sector, and reliability centered maintenance that is crucial in complex, down-time critical plant, and that differentiates failure response/prevention strategies into preventative, predictive, design-out and breakdown (operate-to-failure).

The previous sections of this chapter provide sufficient background information on tools, systems, and teams to address the inadequacies of many corrosion management processes but emphasis is still lacking on the regular auditing of corrosion management systems, the development of effective corrosion mitigation strategies and the control of operational, day to day activities. Successful organizations combine a strategic and tactical culture with daily operations conducted within a responsive, principles-based corrosion management system by competent personnel. As a result, they are enabled to practice cost-effective, predictive/condition based maintenance strategies that incorporate risk-based approaches to inspection. Weaker organizations tend towards an emphasis on tactical issues and less transparent management systems, resulting in a high reliance on expensive, breakdown/repair maintenance strategies.

## Acknowledgments

The author wishes to express his appreciation to Gareth John and Neil Rothwell for informative

discussions of various aspects of the subject area over many years and also to Tony Richardson for helpful editorial comments on this chapter.

### 4.32.1 Materials Selection in the Design Process

#### 4.32.1.1 Overview

The selection of materials, including the processes by which they are shaped, joined, and finished, is integral to the design process through its various stages. In the early, conceptual stages of design, selection of materials is focused primarily on identifying the classes of materials (metals, polymers/elastomers, ceramics/glasses, composites, etc.) that will be used to construct the product. As the process progresses through detailed design, procurement and fabrication/construction, materials selection converges in line with the design process, through subclasses of materials (stainless steel, polypropylene, alumina, glass-reinforced polyester resin, etc. to specific grades of material (SA-516 grade 70 steel, EN 1.4404 equivalent to AISI 316L stainless steel, etc.) and the specific processes that are to be employed in their shaping, joining, and finishing.

Successful selection of materials is based upon identifying and delivering the key materials property and performance requirements of the product that is being designed with regard to:

1. *Functionality* – appropriate combinations of physical, thermal, mechanical, electrical, and/or magnetic properties in combination with appropriate formability and ease of fabrication.
2. *Appearance* – appropriate formability and ease of fabrication with surfaces amenable to appropriate finishing that might include processes such as coloring, patterning, and texturing.
3. *Durability* – predictable resistance to fracture, wear, corrosion, or other deterioration processes throughout the design life of the product.
4. *Economy* – acceptable cost and availability.

The progressive convergence into details, as the design process proceeds, requires increasing precision in the data on which the final materials selection is based and, when the final selection is made, it is vital that the grade of material specified should ensure the delivery of the required combination of properties and performance.

#### 4.32.1.2 Grades of Engineering Materials

The process for identification of specific grades of materials varies with the class of the material. Materials usually have a common name such as stainless steel, brass, bronze, polypropylene, alumina, etc. For example, brasses and bronzes are alloys of copper with zinc and tin respectively. Apart from the fact that different grades of brass and bronze have different properties, this method of identification is inconsistent. For example, manganese bronze contains no tin at all. Clearly, more precise methods of identification beyond common names are required for specific grades of materials.

In the case of metallic materials, there is a long history of identifying specific grades of material by national standardizing societies, trade associations and individual users and producers of metals and alloys, usually by some form of alphanumeric designation. For example, the numbering system for stainless steels based on composition ranges, typified by the 300 (e.g., 304 or 316) and 400 (e.g., 430) series, was introduced originally by the American Iron and Steel Institute (AISI) and is widely adopted internationally by stainless steel specifiers and users. These grades are not specifications in themselves but have been widely used by standardizing bodies such as the American Society for Testing and Materials (ASTM) to identify grades of stainless steel products such as sheets and plates, bars, tubes, etc. More recently, ASTM in collaboration with the Society of

Automotive Engineers (SAE) introduced a unified numbering system (UNS)<sup>2</sup> for metals and alloys that have a ‘commercial standing’ which correlates the various national designations into a single system. The UNS numbers attempt to incorporate widely adopted, historical designations. Thus, the UNS numbers for the AISI grades 304, 316, and 430 stainless steel are S30400, S31600, and S43000 respectively. Most, but not all, metals and alloys have a UNS number but new or developing alloys take time to acquire a number and producers may have proprietary alloy grades that they prefer to identify by a trademarked name.

The identification of nonmetallic classes of materials is much less standardized than in the case of metals and alloys. Thus, there are no recognized designations based on composition or other properties for materials such as polypropylene or alumina. Instead there are many grades of polypropylene and alumina that are specific to commercial suppliers, the compositions and properties of which might vary significantly. Thus, the selection of nonmetallic materials converges to the consideration of specific grades earlier in the design process than is necessary for metallic materials.

#### 4.32.1.3 Materials Selection in Mechanical Design

In the specific area of mechanical design, Ashby and his coworkers<sup>3</sup> have developed systematic approaches to the selection of materials based upon ‘material selection charts’ in which one key property of the material is plotted against another. Materials are represented as elliptical areas that define ranges of values for the properties in question. Performance indices that define quantitative selection criteria can be plotted on the charts, allowing identification of those materials that comply with the selection criteria.

An example of a materials selection chart for safe design against fracture, such as would apply in the case of pressure vessel design, is shown in [Figure 1](#), in which fracture toughness is plotted against strength. Two performance indices have been applied to the chart based on the selection criteria, yield before break ( $M_1 = K_{IC}/\sigma_f = 0.6 \text{ m}^{1/2}$ ) and minimum strength ( $\sigma_f = 100 \text{ MPa}$ ) and as a result a ‘search region’ for candidate materials has been defined. It is clear from the chart that the combinations of fracture toughness and strength that are required for pressure vessels to operate safely are confined mostly to metallic and a few composite materials. Despite

**Figure 1** Materials selection chart for safe design of pressure vessels to avoid fracture. Adapted from Ashby, M. F. *Materials Selection in Mechanical Design*; Butterworth Heinemann, 2005.

their generally excellent corrosion resistances, polymers and elastomers lack the strength and ceramics and glass the ductility to qualify as materials for pressurized systems, although both classes of materials find use as coating and/or lining materials on tougher, steel substrates.

This approach is extremely powerful for the selection of materials in the designing of engineering applications where the key material properties fall into either of the following categories:

1. Invariant properties such as density, stiffness, heat capacity, etc. that do not change as a function of the material's condition, for example, in the case of

an alloy whether the material is annealed, work-hardened, quenched, etc.

2. Deterministic properties such as yield strength, hardness, fracture toughness, electrical conductivity, etc. that vary significantly as a function of the material's condition, but for a given condition of heat treatment, mechanical deformation, etc. are invariant.

However, the approach is less powerful in engineering design applications where the key property of the material is nondeterministic and the property depends on some other parameter that is external to the material or its condition, such as the environment

in the case of corrosion performance. In that case, the Ashby approach at its current stage of development is confined usually to assigning only broad performance categories against broad classes of corrodents and is thus of rather limited use for applications relating to specific environmental conditions.

#### 4.32.1.4 Contribution of Design Codes to Materials Selection

The design of infrastructural or industrial structures/components that present significant safety, health, or environmental (SHE) risks in the event of failure is governed generally by international or national design codes. These codes have mandatory status in most countries and provide rules and guidance on detailed design, including aspects of materials selection, based on experience and technical analysis. Design codes are updated periodically to incorporate learning from accumulating experience and technology advances. The codes are approved and updated by standing committees of the various stakeholders in the design and operation of the equipment governed by the design code, and specific equipment designers, purchasers/operators, suppliers/fabricators, and inspection/regulatory authorities.

Design codes focus on the functionality and safety of the equipment that goes into service. For example, in relation to mechanical design, codes provide rules to reduce to acceptable levels, the risks of failure by brittle fracture or ductile overload as the equipment enters service or by fatigue or creep during its design life. In relation to materials, this is achieved by specifying limiting allowable values of relevant properties, for example, design stresses based on maximum proportions of yield or ultimate strength, toughness based on minimum impact energy or fracture toughness and fatigue/creep lives, based on relevant cyclic stressing and stress rupture properties. Design codes also provide rules and guidance on the fabrication of materials.

A historical example of the successful application of a design code is shown in [Figure 2](#) that shows the aftermath of a hydraulic pressure test applied to a pressure vessel as the final proof of its suitability for service. In the event, the steel vessel failed catastrophically by brittle fracture that initiated as fabrication defects in the heat affected zones of welds that had been inadequately heat treated, resulting in low toughness of the material in the presence of high residual stresses. Although a disaster from the commercial standpoint, the event was a victory for the

**Figure 2** Catastrophic failure of a pressure vessel during final hydraulic test – an example of a commercial disaster, but a successful application of a design code preventing a potentially unsafe piece of equipment from entering service.

relevant design code, because a potentially unsafe vessel was prevented from entering service.

Design codes rarely provide rules or significant guidance for the selection of materials to avoid failure by wear or corrosion processes in service. Their treatment of these matters is normally confined to cautionary advice to consider these potential deterioration processes, and provide appropriate thickness allowances and protection measures to reduce the risk of failure to acceptable levels if necessary. It follows that the mitigation of corrosion risks by materials selection has to be based on knowledge and data from other sources.

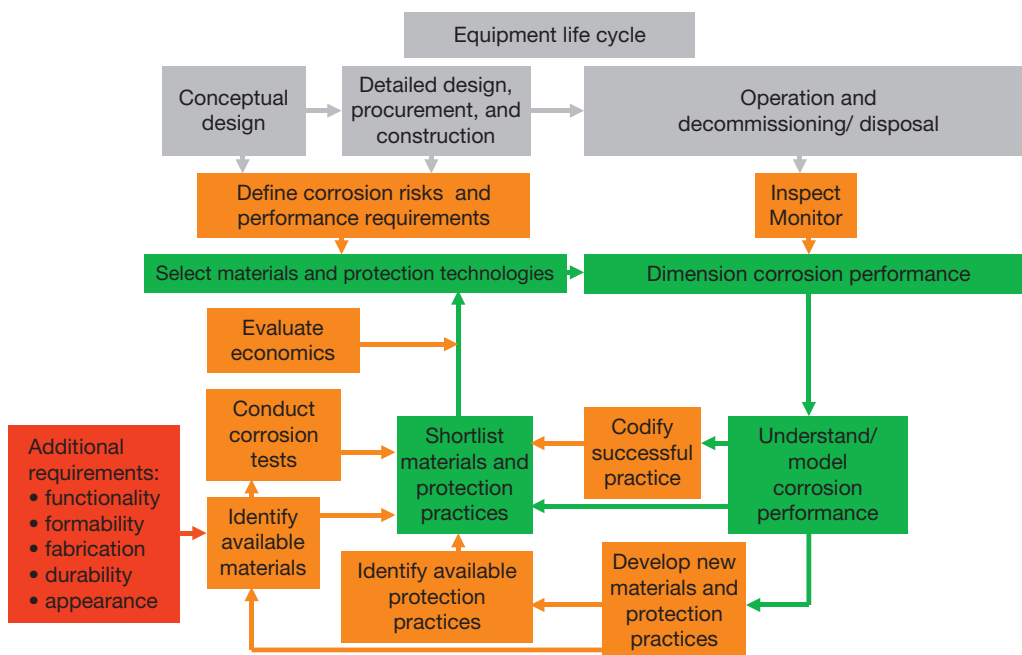

#### 4.32.2 Mitigating Corrosion Risks by Materials Selection

##### 4.32.2.1 The Process

A corrosion risk can be defined as the product of the probability and consequences of a specific corrosion outcome. An overall process for mitigating corrosion risks by the selection of materials and associated corrosion protection measures is shown schematically in [Figure 3](#).

At the design stage, the selection of materials and corrosion protection measures in specific applications can be divided into four stages:

1. The first stage is to define fully the environment. In most applications, the important contributors are the thermal, mechanical, and chemical conditions that the equipment has to withstand for

**Figure 3** Outline process for managing corrosion risks by materials selection.

design purposes and during operation. In some situations, for example, in the process industries, there can be uncertainties in defining environments in terms of their phase and full chemical compositions, particularly during start up, shut down, and transient conditions. Other environmental factors may also contribute. For example, the microbiology of the environment may be important and radiation fields can have important effects on the performance of the materials such as the potential effects of solar radiation on the deterioration of polymeric materials.

2. The second stage is to define performance criteria for candidate materials. The basis for this is the design life, but criteria will vary depending on the application. For example, in applications where appearance or purity is a dominating requirement, corrosion rates that are very small may still be unacceptable. In other applications, higher corrosion rates may be acceptable as long as they do not jeopardize functionality during the design life.
3. In the third stage, credible corrosion risks are identified and evaluated and the corrosion performances of materials that satisfy other critical requirements, such as thermal and mechanical properties, are predicted based on data obtained from experience and testing. Protection measures that are required to control or prevent specific

corrosion outcomes are identified. A shortlist of candidate materials and their required corrosion protection measures is identified.

4. In the final stage, cost and availability data are factored into the decision process to identify the most economic combination of material and corrosion protection measures.

#### 4.32.2.2 Predicting Corrosion Performance

##### 4.32.2.2.1 Identifying credible corrosion risks

The starting point in the prediction of corrosion performance is the identification of credible corrosion risks to the equipment under consideration. This is achieved by considering and evaluating the vulnerability of the equipment to deterioration or failure by the various types of corrosion that can be classified as follows:

1. Uniform corrosion resulting in general thinning or loss of strength.
2. Localized corrosion of passive or oxidized materials resulting in damage mechanisms such as pitting or intergranular corrosion or 'breakaway' oxidation, possibly initiating after an induction period.
3. Stress-induced corrosion promoted by static fabrication stresses and/or static or cyclic operating loads resulting in environmentally assisted damage

mechanisms such as stress corrosion cracking or corrosion fatigue.

4. Flow-induced corrosion promoted by velocities beyond 'critical' levels and the presence of second phase particles such as bubbles, droplets, or solids and the presence of flow disturbers, resulting in damage mechanisms such as erosion-corrosion or cavitation.
5. Galvanic corrosion promoted by the coupling of dissimilar materials including the breakdown/transpassivation or activation of passive metals due to coupling with more noble or active materials respectively.
6. Corrosion processes to which wear is a contributory factor.

Initial assessment of possible corrosion outcomes is based on the basic design characteristics of the equipment under consideration in relation to its design and operating environment, thermomechanical loadings, etc. However, corrosion risks can be influenced significantly by local thermomechanical and process conditions that may be less obvious at the design stage. For example, corrosion processes can be initiated by the development of microenvironments with compositions very different to the bulk fluid at locations such as heat transfer surfaces or in crevices and beneath deposits. The importance of detail in designing, in the recognition and mitigation of corrosion risks is described in a separate chapter and it is important that such considerations are factored into the assessment of possible corrosion outcomes for equipment.

#### **4.32.2.2.2 Performance prediction based on experience**

The most reliable predictor of a material's performance is previous experience of the material in an identical or similar application. The capture and dimensioning of the materials performance in operating equipment by appropriate inspection and monitoring, as illustrated in [Figure 3](#), contributes significantly to the understanding and modeling of corrosion behavior. Feedback of the acquired knowledge results in a more reliable selection of materials in the design process and contributes to the development of new and improved materials and protection procedures.

In risk-aware organizations, corporate corrosion experience and knowledge is embedded in the databases that underpin the procurement and maintenance of assets that capture history and learning. This focuses attention on specific materials/corrosion vulnerabilities, resulting in increasingly reliable

design, and corresponding reductions in maintenance costs. This data is usually captured in a what-works-where format related to specific types of equipment or sometimes more generally related to specific environments as exemplified in [Figure 4](#) that summarizes a particular organization's view of the areas of usefulness of various materials in sulfuric acid.

In the cases of generic corrosion risks in specific applications/industries, industrial knowledge and experience and best practices for mitigation have been extensively codified in industry guides and recommended practices published under the auspices of bodies such as the National Association of Corrosion Engineers (NACE),<sup>4</sup> the European Federation of Corrosion (EFC),<sup>5</sup> and numerous, industry-specific bodies. Many of these sources relate to materials selection, including materials condition requirements, for specific environments. For example, the recommendations of NACE relating to the avoidance of stress corrosion cracking in the use of carbon steels for caustic soda service are summarized in [Figure 5](#).

Informal industry networks are a further source of experiential knowledge on corrosion risks. Conferences can be as useful for networking as for the formal sessions and the email addresses and telephone numbers of other professionals in the field are particularly valuable potential sources of corrosion experience.

#### **4.32.2.2.3 Performance prediction based on corrosion testing**

In the absence of relevant experience, recourse must be had to the results of tests of the performances of materials. There are several published compilations of corrosion test data<sup>6-12</sup> and all materials suppliers provide performance data based on tests for a wide range of corrosive environments. Such data are usually presented as tables or maps of corrosion performance.

Data tabulations usually provide only an indication of the corrosion rate, or of a corrosion performance grading, over a range of corrosion rates. An example of corrosion data tabulation for mixtures of acetic acid + sodium chloride ( $\text{CH}_3\text{COOH} + \text{NaCl}$ ) is shown in [Table 1](#).

More detailed materials performance guides are usually based on mapping approaches, where the corrosion property of interest such as corrosion rate or resistance to a specific form of corrosion, such as crevice corrosion or stress corrosion cracking, is mapped on a field or in a space defined by key environmental parameters. Two- or more dimensional,

**Figure 5** Temperature and concentration limits for stress corrosion cracking susceptibility of carbon steels in caustic soda. Adapted from *Corrosion Data Survey – Metals Section*, 6th ed.; National Association of Corrosion Engineers, 1985.

isocorrosion maps in which lines of constant corrosion rate are plotted as functions of the temperature and concentration of a corrodent are the commonest forms, a typical example of which is shown in [Figure 6](#) that presents isocorrosion curves for various stainless steels at a rate of  $0.1 \text{ mm year}^{-1}$  in formic acid.

Corrosion tables and maps can be useful guides to performance but, in the absence of detailed information regarding the test conditions relating to the data, are no more than that. A corrosion rate from a table or map is unlikely to define fully the corrosion performance of a component in an environment unless the test procedure that generated the result replicates all of the potential contributing influences on corrosion performance in the specific application such as material condition, stress, flow, and heat transfer.

Corrosion testing is the subject of a separate chapter in this book. There are two broad approaches to testing:

1. Laboratory tests that attempt to quantify the performances of candidate materials in simulated or sampled service environments.
2. Tests/trials in prototype or operating equipment.

**Table 1** Corrosion performances of various materials in mixtures of acetic acid and sodium chloride

**Figure 6** Isocorrosion diagram of  $0.1 \text{ mm year}^{-1}$  for various grades of stainless steels in formic acid. Adapted from MTI Publication MS-2 *Materials Selector for Hazardous Chemicals Vol. 2: Formic, Acetic and Other Organic Acids*; Materials Technology Institute of the Chemical Process Industries Inc., St Louis, 1997.

Laboratory tests have inevitable limitations for predicting corrosion performance. The commonest, simplest tests<sup>13</sup> involve exposure of small coupons of material, possibly preloaded, to fluids in heated glassware at atmospheric pressure, with only intermittent fluid refreshment. The maximum test temperature is the fluid boiling point, and the scope for simulation of the effects of factors such as flow, the presence of crevices, or the effects of heat transfer is very limited. More complex experimental arrangements involving the uses of autoclaves, heated and/or rotating test pieces, flowing fluids, etc. have been developed to address such limitations, but practicality and cost considerations usually dictate that such tests focus on a particular subset of contributory factors at the expense of others.

Where the lead times for corrosion testing are short, or in an attempt to increase the credibility of performance prediction, accelerated corrosion tests may be considered in which tests are conducted using intensified variables such as increased temperatures, stresses, concentrations of corrosive species, etc. to accelerate corrosion processes. It is vital in such testing that the possible deterioration and failure modes that are being evaluated should not be altered by the intensified test conditions. Staehle<sup>14</sup> has reviewed the advantages and potential pitfalls of accelerated testing for evaluating nuclear industry corrosion processes.

It is obvious that the inherent limitations of laboratory testing dictate that a degree of judgment is

necessary in their use for the prediction of long term performance. However, this can also apply to performance data obtained from operating experience. This is illustrated in Figure 7, which compares the measured stress corrosion cracking resistances of austenitic stainless steels in neutral solutions in laboratory tests<sup>15</sup> with the incidences of stress corrosion cracking in stainless steel shell and tube heat exchangers in water cooling systems for periods up to >10 years.<sup>16</sup> The laboratory tests were relatively simple, involving exposure of types 304/304L/316/316L stainless steels under constant loads equivalent to yield strength to oxygenated, chloride solutions at various concentrations and temperatures for 1000 h. The data set for the >700 heat exchangers included all the basic austenitic grades operating in a wide range of water compositions and configurations for extended periods and, *per se*, incorporated the accelerating effects of heat transfer, crevices, etc.

In the event, the two performance curves in Figure 7 are relatively close, the major difference being in the predicted minimum temperatures for cracking of  $\sim 50$  and  $\sim 30^\circ\text{C}$  for the laboratory test solutions and operating heat exchanger surfaces (skin temperatures) respectively. On the basis of the data in Figure 7, the laboratory tests might be construed as insufficiently conservative in relation to maximum skin temperature to avoid stress corrosion cracking. However, the operating experience data set also contains some inherent uncertainties and conservatism. For example, the skin temperatures are calculated, rather

**Figure 7** Resistances of austenitic stainless steels to stress corrosion cracking in neutral solutions in 1000 h lab tests<sup>17</sup> and in heat exchangers in recirculating cooling systems for periods up to >10 years.<sup>18</sup>

than measured, and the water compositions cover a wide range, short of brines and seawater. In practice, a maximum skin temperature of  $\sim 50^\circ\text{C}$  is widely considered as acceptable in the process industries for the avoidance of stress corrosion cracking of austenitic stainless steels in waters of potable quality over a 10-year design life and this is closer to the laboratory tests than the experience data set.

Notwithstanding the latter point, tests or trials in prototype or operating equipment allow for the mitigation of most of the inherent deficiencies associated with laboratory tests. Test coupons can be installed in racks that are bolted or welded onto appropriate components or onto retractable coupon holders. Their exposure to the service environments eliminates the risks relating to the environment in laboratory tests such as failing to include undefined constituents or time dependent chemistry changes in nonrefreshed liquors. However, the use of coupons does not eliminate simulation deficiencies relating to fluid flow characteristics, component geometry/stress, heat transfer effects, etc.

The most reliable option for testing materials is the use of trial components in prototype or operating equipment such as spool pieces in piping, impellers in pumps, tubes in heat exchangers, paddles on agitators, etc. Clearly, full scale trial components provide perfect simulation of all the contributory factors

to corrosion. However, their use introduces risks of premature component failure, resulting in possible equipment damage and downtime, the consequences of which have to be evaluated and accepted.

#### 4.32.2.2.4 Performance prediction based on material composition

Research studies of the performances of metallic materials in specific corrosion environments often generate correlations between materials resistance and alloy composition. Probably the most widely recognized correlation is the pitting resistance equivalent number (PREN), first introduced in 1969 by Lorenz and Medawar<sup>17</sup> and updated and refined by many authors since then, that relates the pitting resistances of stainless steels and nickel alloys to their compositions using linear formulas of the general form:

$$\text{PREN} = \% \text{Cr} + m\% \text{Mo} + n\% \text{N}$$

The most commonly used values of  $m$  and  $n$  are 3.3 and 16, respectively, although some versions give more weighting to nitrogen for specific grades and for superduplex stainless steels and nickel alloys the concentrations of tungsten and niobium are also weighted.

Correlations of this type are completely empirical and, although very useful for ranking and comparing candidate alloys, they are not a reliable basis for predicting the materials performance in specific applications where the corrosion outcome for which they were developed is a risk.<sup>18</sup>

#### 4.32.2.2.5 Performance prediction based on quantitative modeling

Performance predictions, based on experience and corrosion testing, are essentially empirical. In industries where the consequences of unpredicted failure have unacceptable SHE and/or financial consequences, such as power generation, aerospace and oil and gas recovery, major expenditures on corrosion research into generic industry corrosion processes can be justified. Such research results in a sufficiently detailed understanding and dimensioning of corrosion processes to allow the development of quantitative models of corrosion mechanisms and such models can be used to predict corrosion performances as functions of relevant contributing variables.<sup>19</sup> Reviewing of the various approaches to modeling is beyond the scope of this chapter and the reader is referred to other chapters in this book that are concerned specifically with corrosion

modeling, specific corrosion processes and the management of corrosion in specific industries.

#### 4.32.2.3 Evaluating Corrosion Risks in Materials Selection

One of the more important requirements of the materials selection process is that the level of risk inherent in a materials recommendation is understood and aligned to the overall philosophy for managing the SHE and commercial risks in specific applications. The extent to which such risks need to be quantified rigorously depends upon the application and in particular the SHE consequences of corrosion failure.

For example, in the process industries, the SHE risk aspects of materials and protection selection are embedded in the hazard study methodologies<sup>20</sup> that evaluate hazards throughout the process and equipment design at its various stages. Such methodologies attempt to ensure that the safety and health risks presented to employees and the public and the contamination risks presented to the environment are contained within acceptable defined limit values. Risks, including those arising from the materials selection, are evaluated and mitigated by teams of functional professionals, including materials/corrosion engineers.

In the process industries, the semiquantitative evaluation of corrosion risks is normally regarded as sufficient, based on the essentially empirical corrosion data that is used to predict corrosion performance, the reliability of which is normally classified as of high, medium or low reliability, depending on the source. For example, the American Petroleum Institute classifies the reliability of corrosion data as follows<sup>21</sup>:

1. *High reliability sources* – extensive field data through inspection, test coupon data from >5 years exposure in operating equipment.
2. *Moderate reliability sources* – laboratory testing with simulated process conditions, limited operating plant corrosion coupon testing.
3. *Low reliability sources* – published data, corrosion rate tables.

In contrast, in the nuclear industry, quantitative corrosion risk assessment is required, consistent with the greater consequences of equipment failure and more demanding acceptable limit values for risk. For example, Staehle<sup>14</sup> has described a 'corrosion based design approach' (CBDA) process for the prediction of materials performance consisting essentially of the

same stages described above, but evaluated to a much greater level of detail using statistical methodologies. This allows a total probability of equipment failure to be calculated as a function of the probabilities of failure, by specific corrosion processes at specific locations in the equipment.

#### 4.32.3 Economic Evaluation in Materials Selection

The costs of materials vary widely and their relative costs vary with time, depending not the least on the cyclical nature of the costs of metals and other raw materials. The cheapest constructional material is usually steel but its limited thermal and corrosion capabilities require consideration of alternative materials in many applications. In highly corrosive applications, expensive materials such as nickel, titanium, zirconium and tantalum alloys may have to be employed. Nonmetallic materials can provide excellent corrosion resistance at a modest cost but have mechanical property limitations that may require them to be used as protective coatings/linings on stronger substrates such as steel.

The procedures that are used to incorporate costs into the materials selection process are described in a separate chapter in this book concerned with the economic aspects of corrosion.

Whatever the application, the scarcity and cost of capital favor selection of the cheapest of the short-listed materials of construction at the design stage. In some applications this is a valid approach. However, in the cases of complex assets it is recognized that the so-called life cycle costing (LCC) procedures are required that factor in the costs of maintenance and potential unreliability associated with the performances of alternative materials of construction throughout the operating life of the assets in the prevailing economic environment.

This is achieved by the use of discounted cash flow (DCF) procedures that provide an appropriate balance between capital and operating costs by factoring in variations in the value of money with time and the requirement for organizations to obtain an appropriate return on their investment. In the DCF process, all capital and operating costs and revenues associated with the assets are discounted to their values in the base year of the investment appraisal and summed to produce a net present value (NPV) for each materials option. On this basis, the most economic material of construction is that which

yields the highest NPV and this is not necessarily the cheapest material of construction.

Application of such procedures produces some general economic truths relating to the selection of materials and corrosion control options:

1. Relatively low interest rates favor long-term economic planning and the cheapest may well not be the most economic option when life cycle costs are taken into consideration.
2. Alternatively, when capital is very expensive, shorter term considerations tend to dominate and large, long-term investments have no merit over small, frequently repeated investments. In these circumstances, the cheapest is also likely to be the most economic option.
3. It is essential that the risks and uncertainties attached to the inputs to a decision are understood and incorporated into the process of identifying the most economic option.

#### 4.32.4 Outputs/Records of Materials Selection Processes

The output of a materials selection process should be much more than one or more proposed grades of materials. A materials selection process should produce and record, as a minimum, the following elements:

1. Materials recommendations, citing relevant specifications and trade names, including alternatives that may be used on the basis of price and availability.
2. Relevant limitations arising from the materials selected and their potential for deterioration such as limiting materials properties, required corrosion allowances, equipment operation limitations and inspection or future repair/replacement requirements.
3. Relevant tests, fabrication, erection, or other requirements to ensure quality and condition and correct use of the materials selected.
4. Defined sources of corrosion and other data, including tests, used in assessing the suitability of materials

In the cases of complex assets consisting of numerous subcomponents such as an airplane or a chemical process plant, it is vital that selections of materials are documented to capture the know-how that they embody, record any changes that are required and render the information accessible to the wider community of engineers and managers concerned with

the design and operation of the assets. For example, in the process industries, the use of materials selection diagrams (MSDs) has been adopted for these purposes<sup>22</sup> that comprise simplified process flow diagrams showing relevant operating conditions together with materials selection information and any associated corrosion protection practices. These diagrams capture the information needed to ensure that decisions for the selection of materials for the many specific items of equipment that comprise the final plant (vessels, piping, machines, instrumentation) incorporate the outcomes of corrosion risk identification and evaluation, together with any necessary mitigation practices, for the relevant operating conditions. This is particularly important when materials selection decisions are spread across several supplier organizations to mitigate the risks of deficient information transfer across organizational boundaries.

#### 4.32.5 Characteristics of Successful Materials Selection for Corrosion Resistance

Materials selection is a complex process of which the predictable resistance to corrosion is but one element. However, there are some general features that differentiate successful from less successful materials selection for corrosion resistance. Success is characterized by:

1. Early, sustained involvement from initial definition of the corrosion environment and performance requirements through design iterations during the conceptual and detailed design stages. In industries such as the process industries, materials selection issues may well influence process development.
2. Incorporation of learning from similar designs/processes.
3. Integration of materials evaluation into laboratory simulations and the development of pilot scale equipment and prototypes.
4. In the case of complex assets, a management process to ensure that materials selection for all subcomponents is informed as to the prevailing corrosion risks and required mitigation practices.

In contrast, less successful materials selection for corrosion resistance is often characterized by:

1. Involvement after the conceptual and even some of the detailed design stages are complete, when

the degrees of freedom for materials selection are much more limited.

2. Failure to incorporate learning from similar designs/processes.
3. Deficient corrosion environment definition, particularly in relation to transient or upset conditions.
4. Deficient corrosion testing/evaluation due to the failure to simulate real operating conditions.
5. Failure to inform the materials selection process for subcomponents of complex assets about the prevailing corrosion risks and required mitigation practices.

### 4.33.1 The Design Process

Design is the process that translates needs or aspirations into products. The need is satisfied or the aspiration realized in some appropriate combination of functionality, appearance, durability, and cost of the designed product that can range from a simple, individual component, such as a fastener or a wedding ring, to a complex system assembled from many individual components, such as an aeroplane or a nuclear power station.

Ashby<sup>1</sup> has differentiated three types of design.

1. Original design that is based on a new working principle(s).
2. Adaptive/developmental design seeking incremental advances in performance through refinements to working principle(s).
3. Variant design involving changes in scale or dimensions without changes in function or methods of achieving it.

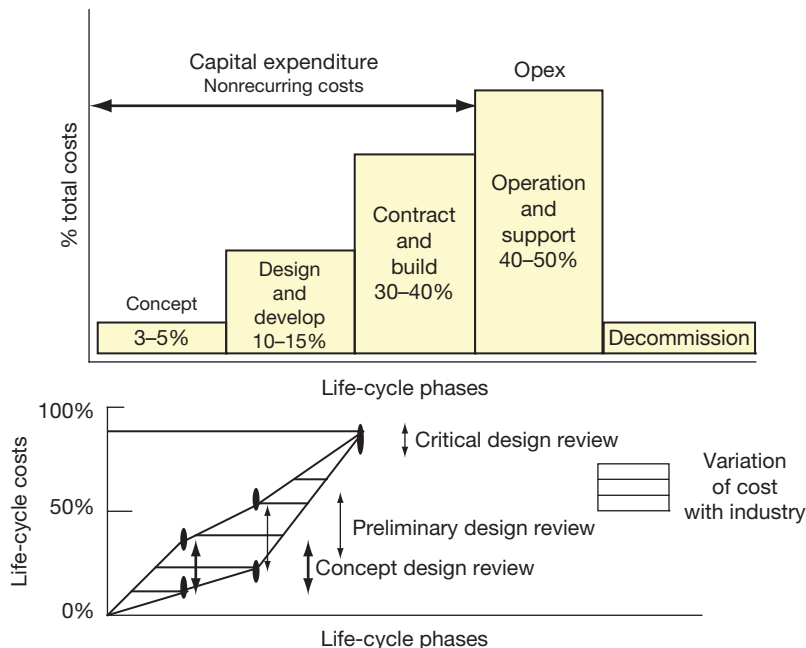

The design process is usually undertaken at the front end of a project life-cycle which then progresses through construction to operation and maintenance and finally to decommissioning, dismantling, and removal of plant and equipment. Depending on the size and complexity of the project, the design process may be broken down into distinct stages of conceptual design, engineering design, and detailing. In practice, there can be considerable overlap of

these stages due to the need to meet specific milestones within the project engineering phase and the iterative nature of the design process. During this process, sometimes referred to as the design loop, the design brief requirements are translated into options which, after detailed, critical appraisal and possible modification/recycling, are reduced to a preferred option that can be subjected to a final engineering review/audit that verifies its viability.

A common objective of the design process is to minimize life-cycle costs. In practice, these are determined early in the design process when major decisions, including the selection of materials and possible corrosion control options, are made. Studies of reliability and maintainability data from various types of projects<sup>2</sup> indicate that 10–25%, 25–60%, and 95% of the life cycle costs are predetermined by the concept design review, preliminary design audit, and final critical design review respectively, the timings of which are shown schematically in **Figure 1**. However, the early design stages account, typically, for less than 20% of the total project budget, and thus, a slight increase in spending on corrosion risk mitigation at the concept and design development stages can pay off handsomely in large cost savings during operation

and even savings during the detailed design and construction stages.

Regardless of the particular application, the early stages of original and adaptive/developmental design processes are divergent in character. Alternative options are explored and evaluated and, where the product is large and complex, a structured process is used, the output of which is commonly described as a front end engineering design (FEED) or similar. A FEED evaluates the feasibility of a potential project and defines its business and technical scope. Thus, a FEED provides an economic justification for the project and a cost/benefit estimate that usually seeks to be accurate to within  $\pm 10\%$  or thereabouts. In relation to the technical scope, a FEED identifies the technology that is to be adopted and the basis for the ensuing detailed engineering design. Regarding corrosion risk mitigation at the FEED stage, it is usually sufficient to identify the likely classes of material that are to be used for products/equipment together with any attendant significant corrosion risks and corresponding mitigation strategies such as the use of protective coatings, anodic or cathodic protection, or process/environmental modification to inhibit corrosion. These evaluations are commonly desktop studies based on published data and computer based models.

**Figure 1** Effect of project phase expenditure on life-cycle costs. Adapted from Kennedy, I. Design and specification for reliability and maintainability; Presented at National Tribology Course on Reducing Plant and Equipment Life-cycle Costs; 24 November 1994.

Projects that are approved to proceed beyond the business feasibility/FEED stage move into the detailed engineering design, procurement, and construction (EPC) phase. At this stage, the design process converges into increasing detail as the functionality, appearance, durability, and cost of the final product or equipment are specified to facilitate manufacture. The detailed design of infrastructural or industrial structures/components that present significant safety, health, or environmental (SHE) risks in the event of failure is governed generally by international or national design codes. For example, much of the world's process and power equipment is designed in accordance with design codes produced by the American Society of Mechanical Engineers (ASME). The codes have mandatory status in most countries and provide rules and guidance on detailed design, including aspects of materials selection, based on experience and technical analysis. Design codes are updated periodically to incorporate learning from accumulating experience and technology advances. The codes are approved and updated by standing committees of the various stakeholders in the design and operation of the relevant equipment, specifically designers, purchasers/operators, suppliers/fabricators, and inspection/regulatory authorities.

In the case of a large, complex project, the detailed engineering may well be undertaken by a specialist contractor who also undertakes procurement and construction – a so-called EPC contractor. During this stage, drawings and data sheets are produced for products or individual equipment items that finalize the detailed thermomechanical and process design in compliance with the relevant code. Design codes focus on the functionality and safety of equipment that goes into service. For example, in relation to mechanical design, codes provide rules to reduce to acceptable levels the risks of failure by brittle fracture or ductile overload as the equipment enters service or by fatigue or creep during its design life. Design codes also provide rules and guidance on the fabrication of materials. However, design codes usually offer little more than general guidance on the mitigation of corrosion risks that also requires detailed consideration at this stage. The specific grades of materials need to be specified along with the procedures and practices that are to be used to fabricate them and protect them from corrosion.

Arguably the most important input to this detailed design stage is feedback of learning from previous operating experience within an organization or an industrial sector relating to causes of equipment or component failure and the success or otherwise of

engineering practices that have been deployed to mitigate the risks of failure. Some of this learning may have been codified in corporate and national/international engineering guides, standards, and specifications. In relation to corrosion risk mitigation, these documents are concerned mostly with the selection of appropriate materials and practices that are available for corrosion protection in specific applications. The selection of materials and protection practices is considered in a separate chapter in this volume.

However, localized thermomechanical effects and process design practices themselves can also have a significant influence on corrosion risk and its mitigation. This is not widely appreciated amongst design engineers and a lack of assessment of these parameters can result in avoidable corrosion problems in service. A significant challenge facing design teams is how to ensure that operating experience of good and bad design practices is fed back into the design stages of new projects through effective communications amongst operating and maintenance staff, design teams, and corrosion specialists.

The activities and information flows that are essential to the successful mitigation of corrosion risks in the design process are summarized in [Figure 2](#), which confirms the crucial significances of the FEED documents and the detailed drawings/data sheets that form the inputs and outputs of the engineering design and detailing stages.

Major corrosion concerns and risk mitigation issues are usually identified and addressed in the reviews and audits of the FEED documents which result from the conceptual and early design stages and are essentially driven by likely life-cycle cost benefits. Good design practices relating to the various thermomechanical and process factors summarized in [Figure 2](#) come into play in the engineering design and detailing stages. They are less codified than is the case for the selection of materials and corrosion protection practices and, crucially, designers often have limited experience of the service performance of equipment that would provide insights into good practices in these areas. Unless such risks are controlled they can have considerable financial implications that are many times those of the budgeted direct cost of corrosion control. In the following sections of this chapter, potential corrosion risks that can arise from poor design are reviewed along with general approaches to the mitigation of such risks by good thermomechanical and process design practices. There are sources that overview the subject,<sup>3,4</sup> the most comprehensive of which is Pludek's book<sup>3</sup>

**Figure 2** Activities and information flows for mitigating corrosion risks by design.

that provides many examples of design practices that exacerbate corrosion risks and corresponding good practices for the mitigation of such risks by detailed design. However, awareness of the need for good thermomechanical and process design practices throughout the design process is not sufficient to deliver effective corrosion risk mitigation unless corrosion issues are managed effectively within the project design process and this is addressed in the final section of the chapter.

#### 4.33.2 Corrosion Risks Arising from Microenvironments

In any particular application, materials are selected relative to a defined corrosion environment, the key contributory factors to which are:

1. fluid chemistries;
2. fluid temperatures;
3. equipment/component stresses;
4. fluid flow characteristics;
5. heat transfer characteristics;
6. location/layout/shape of equipment and components.

These factors that define the macrocorrosion environment are interactive. Thus, fluid flow characteristics are dependent on shape, heat transfer characteristics on fluid temperatures, etc. The performance of a specific material in a particular application will be determined by clusters of the various factors that will vary with the application. For example, fluid flow and heat transfer are particularly relevant to the process and power generation industries. Clearly, if a piece of equipment is to be fabricated from several different materials, then there are additional corrosion risks arising from potential galvanic interactions that have also to be evaluated and mitigated.

All of the contributory factors are, in theory, degrees of freedom in the design of a component or a piece of equipment for a particular application. In practice, fluid chemistries and temperatures are predetermined in many applications, but the dimensions and characteristics of the other factors can all be influenced by the detailed thermomechanical and process design of equipment and components. Materials selection *per se* is rarely sufficient. It needs to be overlaid with good design practices if corrosion risks are to be mitigated in subsequent operation.

The recognition of corrosion risks relating to the macroenvironment at the design stage is relatively straightforward. However, as illustrated in [Figure 3](#), all of the contributory factors can intensify and interact locally in equipment and components. Thus, fluids may condense locally at cold spots to produce chemistries that are much more corrosive than the bulk chemistry of the fluid. Stresses may be concentrated significantly by fabrication and other defects in equipment and components that may increase the risks of initiation of environmentally assisted cracking. Local shape features may disturb fluid flows with significant outcomes regarding the vulnerability of components to erosion–corrosion. In practice, these intensified local factors can also cluster to define local microenvironments that present much larger corrosion risks than clusters of the equivalent bulk factors. Such microenvironments can be much more difficult to predict at the design stage and are a common source of unscheduled failure of equipment due to corrosion.

#### 4.33.3 Mitigation of Risks Arising from Chemistry Definition/Control

The commonest cause of unpredicted corrosion problems is the failure to define accurately the chemistries of environments or to anticipate changes in chemistry that are caused by other prevailing factors at specific locations in equipment. The major

1. Variations in bulk chemistry may occur with time, under climatic influences, or during start-up, shut-down, or upset conditions in operation. For example, in the process industries, the lives of carbon steel reactors that are used for the manufacture of ethylene dichloride are determined almost exclusively by the incidence or otherwise of condensation of hydrochloric acid during start-up, in sharp contrast to the steady state operating environment, where corrosion rates are low.<sup>5</sup> It is important that potential changes in bulk chemistry with time are defined, quantified, and evaluated at the design stage.
2. The presences and concentrations of minor components may dominate corrosion performance. For example, the performances of passive alloys in reducing acid solutions are influenced strongly by the presences or otherwise of oxidizing metal ions (favorably) or chloride ions (unfavorably) at relatively low levels in the tens to hundreds ppm range.<sup>6</sup> It is important that minor components are defined, quantified, and evaluated at the design stage, including their possible local concentration such as in distillation and separation equipment.
3. Local shape and/or heat transfer may promote the development of local chemistries that are very different from and much more corrosive than the bulk fluid chemistry, in particular where phase changes may occur. Early condensates from acid gas/vapor streams can be very concentrated and corrosive relative to bulk condensates as in the cases of combustion flue gases,<sup>7</sup> and refinery overhead streams.<sup>8</sup> Initially benign condensates or cooling fluids can concentrate due to intermittent contact with surfaces hot enough to promote concentration or dry-out, as in the chloride-induced, external stress corrosion cracking of austenitic stainless steels under thermal insulation.<sup>9</sup> Extremely high concentration factors are possible under boiling heat transfer in crevices or under deposits, or under film boiling conditions at high heat flux regions, as in water side, on-load corrosion in process and utility boilers.<sup>10</sup>

A typical example of potential microenvironment development under the combined influences of shape and heat transfer is the shell and tube heat exchanger that is widely used for cooling and heating applications in the process and power industries.

The critical design feature of these exchangers is the tube/tube-plate joint that separates the two working fluids and which almost inevitably contains a crevice, unless it is eliminated by employing expensive fabrication procedures. Sections of a typical shell and tube cooler fabricated with welded tube/tube-plate joints using shell-side water as the cooling medium are shown schematically in [Figure 4](#) in a vertical configuration, characterized by the existence of a vapor space between the water exit and the upper, hot tube-plate.

The chloride contents of waters vary over many orders of magnitude, depending on the source. Demineralized waters and condensates generally contain <1 ppm chloride. Lake waters commonly contain low levels of chloride in the range 1–10 ppm, potable waters in the range 10–100 ppm, rivers in the range 100–1000, and estuarine and seawaters in the range 1000–10 000 ppm. During operation, cooling water splashes onto the underside of the hot tube-plate, where it evaporates to dryness. Successive events result in the accumulation of scale/salt deposits, in which the concentration of chloride is many orders of magnitude greater than in the bulk cooling water. The crevices between the tubes and the tube-plate provide for retention and further concentration of aqueous fluid.

The thin tubes contain residual stresses equivalent at the yield strength of the material, arising from tube expansion and welding of the joint during fabrication.

It follows that if, as is commonly the case, the heat exchanger is constructed in austenitic stainless steel, the microenvironment that develops in and around the tube/tube-plate joint introduces significant risks of chloride-induced stress corrosion cracking, particularly within the crevice, as illustrated in [Figure 4](#).

There are several approaches to mitigating these risks, the most direct of which is the selection of ferritic or duplex austenitic–ferritic grades of stainless steel that are more resistant or even immune to chloride-induced stress corrosion cracking. However, there are also practical design measures that can be used to mitigate the risks for austenitic stainless steels. As confirmed in [Figure 5](#), risks are significantly lowered in horizontal relative to vertical heat exchangers because the vapor space that is the essential cause of microenvironment development is removed.

Risks are further lowered if the cooling water is transferred to the tube-side, because the tube/tube-plate crevice that contributes to microenvironment development is eliminated. If the exchanger, for other reasons, has to be vertical with shell-side cooling, risks can be lowered by venting the hot tube-sheet, thereby eliminating the vapor space, as shown schematically in [Figure 6](#).

#### 4.33.4 Mitigation of Risks Arising from Thermal Design

The bulk temperature of an environment can usually be predicted accurately, notwithstanding the need to incorporate, if appropriate, the influences of

**Figure 4** Creation of microenvironments that promotes stress corrosion cracking by repeated wetting/drying events in the tube/tube-plate regions of vertical, austenitic stainless steel heat exchangers with shell-side water.

**Figure 5** Resistances of austenitic stainless steel heat exchangers to chloride induced stress corrosion cracking in open, recirculating cooling systems for periods up to >10 years. Adapted from Haruyama, S. *Mater. Perform.* **1982**, 21, 14–19.

**Figure 6** Prevention of microenvironments that promote stress corrosion cracking in the tube/tube-plate regions of the shell-sides of vertical shell and tube heat exchangers by venting the top tube-sheet.

time-dependent factors such as climatic conditions, or start-up, shut-down, or upset conditions during operation. The possible effects on local temperatures of fluid mixing need to be recognized. For example, the addition of acids to process streams may be characterized by significant dilution exotherms that produce a much hotter, local microenvironment with additional corrosion risks which may have to be mitigated by a local materials upgrade at the design stage.

Heat transfer introduces additional factors that need to be evaluated. The case of heat transfer from a fluid to a solid wall controlled by convective/turbulent flow with fluid eddies, and through the solid wall by conduction, is shown schematically in [Figure 7](#). The local heat flux is given by:

$$q = h_1(T_1 - T_2) = k_w/x_w(T_2 - T_3) = h_2(T_3 - T_4)$$

**Figure 7** Temperature profile for the case of heat transfer between fluids and a solid wall controlled by turbulent flow/convection ( $h_n$ ), through the solid wall by conduction ( $k_w/x_w$ ).  $T$  = temperature (K);  $k$  = thermal conductivity ( $\text{W m}^{-1} \text{K}^{-1}$ );  $x$  = wall/film thickness (m);  $h_n$  = fluid to wall heat transfer coefficient ( $\text{W m}^{-1} \text{K}^{-1}$ ).

where  $q$  is the heat flux ( $\text{W m}^{-2}$ );  $h_n$ , the film heat transfer coefficient ( $\text{W m}^{-2} \text{K}^{-1}$ );  $T$ , the temperature (K);  $k$ , the thermal conductivity ( $\text{W m}^{-1} \text{K}^{-1}$ );  $x$  is the wall thickness (m).

From the design standpoint, heat transfer is promoted by low thickness and high thermal conductivity of the solid wall, high values of  $\Delta T$  ( $T_1 - T_4$ ) and turbulence that generates high values of  $h_n$ . One of the more important features of heat transfer in relation to its corrosion effects is the difference between metal surface, or skin temperatures,  $T_2$  and  $T_3$ , and the bulk fluid temperatures,  $T_1$  and  $T_4$ , as depicted schematically in [Figure 7](#).

There are additional potential corrosion risks arising from the effects of heat transfer. Heat exchangers typically operate under relatively high flow rates to promote turbulent flow conditions, resulting in reduced boundary layer thickness. The supply of reactants, or the removal of intermediates or products, is dominated by flow-induced mass transfer. In single phase fluids, the overriding additional effect of heat transfer is the influence of wall temperature on diffusion coefficients and viscosity. These influence boundary layer thicknesses and concentration profiles and the stabilities, solubilities, and compositions of the relatively thick diffusion barrier layers which are continuously penetrated by turbulent eddies and localized areas of high turbulence intensity at tube inlets, downstream of protrusions and other changes of shape. These not only increase heat transfer rates but have controlling effects on the corrosion and erosion-corrosion of metals such as steels and copper alloys in specific applications.<sup>11</sup>

For example, heat transfer to a liquid makes it more difficult to transfer oxygen from the bulk solution to a hot wall surface because of the reduced solubility of oxygen as temperature increases. In cases where the solubility product increases with temperature, heat and momentum transfer at the wall-liquid interface may tend to undermine and detach protective barrier layers, whilst encouraging thickening of scales by diffusion and precipitation at the outer face. Conversely, where the solubility

product decreases with temperature, heat transfer to a liquid may promote the formation of adherent, thin scales, the classic case of which is the formation of calcium carbonate and sulphate scales on heat transfer surfaces in cooling waters.

Wall conditions can also be influenced by whether the heat exchanger design is co-current or counter current as local wall temperatures may be higher than indicated by average design figures. The design will allow for a fouling factor to account for lower overall heat transfer rates during operational life. These apparently minor differences on the process design flow sheet can result, in practice, in significant changes to local microenvironments that give rise to corrosion.

Heat transfer is also promoted by phase changes such as boiling or condensation and these can, as noted previously, promote the formation of local environments with significant additional corrosion risks. For example, modern high pressure boilers are designed utilizing high heat fluxes, typically  $1000 \text{ kW m}^{-2}$  that can promote film boiling conditions that result in fouling/corrosion processes during operation (on-load), depending on the efficacy of the prevailing boiler water treatment. Process plant boilers are commonly designed with particularly high heat fluxes to reduce capital costs, and can therefore be particularly vulnerable to on-load corrosion, as illustrated schematically in Figure 8 for a typical, horizontal, fire-tube boiler constructed in carbon

**Figure 8** Creation of corrosion-promoting microenvironments at high heat flux regions of horizontal, fire tube boilers resulting in on-load corrosion.

steel that uses a hot process gas, typically entering at  $\sim 1000^\circ\text{C}$ , to raise steam from water on the shell-side at a typical pressure of  $\sim 100$  barg.

The boiler depicted in **Figure 8** would typically be designed with average heat fluxes of  $\sim 3000\text{ kW m}^{-2}$ , increasing to  $\sim 6000\text{ kW m}^{-2}$  locally, and would operate on fully demineralized water. The hot channel end and tube-plate would be refractory clad to maintain the carbon steel temperatures within the code design range, with the tube temperatures determined largely by the boiling water temperature,  $\sim 310^\circ\text{C}$ . A typical tube entry construction detail is illustrated in **Figure 8**, consisting of high temperature alloy ferrules set into the tube-sheet refractory and extending some distance into the tubes, separated from them by an insulating material. The ferrules are required to protect the tube inlet regions from excessive heat flux by providing a transition region to reduce the inevitable region of enhanced heat transfer just beyond the ferrule to within the design requirement.

The corrosion rate of carbon steel in boiler waters at  $\sim 310^\circ\text{C}$  depends on the solubility of magnetite, and therefore pH. It is known that concentrated acidic or alkaline solutions can form at local sites where convection/mixing are restricted, such as crevices at tube/tube-plate joints, on horizontal or inclined surfaces, or at flow disturbances such as tube bends or weld protrusions. Steam blanketing under film boiling conditions can result in intermittent wetting/drying and solute concentration by several orders of magnitude, exacerbated by porous deposits such as oxides of iron or copper that promote so-called wick boiling. Concentrated alkaline solutions usually arise from concentration of alkaline corrosion inhibition species from which free sodium hydroxide can be liberated, particularly sodium phosphate treatments. Concentrated acid solutions arise when bulk contamination of the boiler water with dissolved oxygen and chloride, typically by sea or river water ingress, occurs. The boiler depicted in **Figure 8** is at risk of such local microenvironments developing on tube surfaces in the regions of maximum heat transfer beyond the ferrules, resulting in pitting and ultimately tube perforation.

In practice, the risks depicted in **Figure 8** can be mitigated by tight control of water chemistry during operation to prevent the formation of highly alkaline or acid environments in the event that film boiling conditions occur. However, the risks can also be mitigated by the attenuation of excessive heat fluxes with an improved design, as depicted in **Figure 9**, which shows an extended, profiled ferrule for that purpose.

**Figure 9** Tube ferrule design to mitigate risks of on-load corrosion due to excessive heat fluxes in horizontal, fire-tube boilers.

#### 4.33.5 Mitigation of Risks Arising from Mechanical Design

Engineering structures are exposed to a range of operating stress regimes, depending on the application. Static structural loadings are usually limited to maximum proportions of yield or ultimate strength of the material at lower temperatures, or stress rupture properties of the material if operating at temperatures within its creep range, as dictated by the relevant equipment design codes. In practice, design codes usually permit higher stresses in local regions of equipment than the maximum allowable specified for the majority of the structure, for example at penetrations through the vessel wall in the case of pressure vessels. Fabrication processes such as cold working and welding can introduce local, static, residual stresses at levels up to and beyond the yield strength of the material.

Equipment may also be required to withstand dynamic loadings. These cyclic loadings may be associated with equipment start-up and shut-down conditions, or may be intrinsic to the application itself, as for example in the cases of marine structures that have to withstand tidal and/or wave loadings, or pressure vessels for processes based on pressure cycling. They may arise indirectly from thermal cycling/transients, particularly under conditions of restricted expansion and contraction. Higher frequency, vibration loadings may be wind excited, or arise from pressure pulsations, or be transmitted from adjacent reciprocating or rotating machinery. In some applications, loading regimes are complex combinations of static and dynamic loadings, as for example in the case of turbine blades that may have to withstand static centrifugal loads at temperatures within

the material's creep range that are overlaid with relatively high frequency, low stress range loadings arising from varying fluid pressures as the blades rotate. As in the case of static loads, equipment design codes provide guidance on the confinement of dynamic loadings to within the appropriate fatigue strength capabilities of the relevant materials.

Where thinning of structural components due to corrosion and/or wear is anticipated in service, appropriate thickness allowances or sacrificial shielding components such as impingement plates may be specified at critical locations at the design stage to ensure that components retain sufficient thickness throughout their service lives to maintain membrane stresses below the design maximum allowable levels. This approach to corrosion risk mitigation is applicable only to relatively thick section components where some loss of section thickness can be tolerated such as major structural members, pressure vessel or pipe walls, etc. It is impractical for thin section components such as heat exchanger tubes/plates, or where dimensional clearances must be maintained throughout service life such as in seals, or where environmental contamination by corrosion products is unacceptable such as in the food and pharmaceutical industries.

The potential risks of environmentally assisted cracking (EAC) have also to be evaluated and mitigated at the design stage. Regions of relatively high static stress, in particular associated with residual fabrication stresses, are preferred sites for the initiation of the various forms of EAC that are described in separate chapters in this book. Corrosion has significant potential influences on the risks of initiation and rates of propagation of fatigue cracks in materials, and both static and dynamic stresses can be concentrated by defects in materials or welds. In the cases of equipment for critical duties such as offshore structures and nuclear pressure vessels, these factors are incorporated formally into relevant design codes. However, for most equipment, the additional risks they promote have to be evaluated and mitigated on the basis of more general engineering good practice.

The general approaches to the mitigation of EAC risks by the control of stress and its concentration are as follows:

1. Design stresses and the sizes of fabrication defects are controlled to levels where the maximum stress intensity for the equipment,  $K_{I\text{design}}$ , is below the critical stress intensity for EAC,  $K_{I\text{EAC}}$ . Given that design codes commonly allow membrane stresses

that are significant proportions of the yield strength of a material, this approach offers limited scope to mitigate risks in many practical situations. An example of its successful use would be the case of steel gas cylinders that are usually hot forged to final shape in one operation in thicknesses well above the minimum required to sustain maximum operating pressures. As a result, they operate with very low applied stresses and contain very small residual stresses and are therefore effectively immune to EAC even when containing environments such as anhydrous ammonia or HCN that are known to present risks of EAC to steels.

2. Stress concentrations are controlled by appropriate control of shape and by confining defect sizes below specified limiting values, for example by the use of transitional radii at changes in cross section such as at notches and key ways, the control of surface finish etc. Welds are the commonest sources of defects in fabricated structures and therefore require appropriate inspection and possible repair to eliminate potentially critical fabrication defects. For particularly critical applications, practices such as the machining/grinding of weld toes to eliminate small defects are specified.
3. Residual/fabrication stresses are controlled by specifying thermal or mechanical stress relief procedures. Thermal procedures have been employed routinely for the relief of fabrication stresses in carbon and low alloy steels using procedures that are detailed in relevant design codes. Typically, structures are heated to temperatures within the range 550–650 °C for short time periods that depend on component thickness. Rules exist that govern rates of heating and cooling, allowable temperature gradients, etc. Ideally, completed structures are heat treated in furnaces, but large structures may have to be furnace treated in sections, and the final welds heat treated locally using electric heating elements. Local heat treatments may not achieve the degrees of stress relief that are achieved with furnace heat treatment. So-called temper bead welding is a special case of local heat treatment in which successive weld beads impart a degree of stress relief to earlier deposits and a final, temper bead heat treats the last of the deposits required for strength purposes. Where thermal stress relief is impractical, or cannot be applied because the material's properties are likely to be altered unacceptably during the process, mechanical procedures can be employed such as

vibratory stress relief or peening. Vibratory stress relief<sup>12</sup> uses high amplitude, resonant vibrations to attenuate and redistribute residual stresses. Peening uses shot or beads,<sup>13</sup> or laser energy,<sup>14</sup> to produce compressive layers over regions of residual tensile stress to prevent the initiation of environmental cracks.

4. Vibrations can be transmitted from one item to another through connecting pipe work and/or supports and may promote high cycle corrosion fatigue and related damage mechanisms. One such example is where standby pumps are attached to the same plinth as the working pump, leading to failure to start on switch over, due to fretting of the bearings. Vibrations are controlled by specifying additional stiffening or support and/or by damping local resonant vibrations.

#### 4.33.6 Mitigation of Risks Arising from Geography/Shape

There are limits to the degrees of freedom governing the geographic location of sites and/or equipment, but geography does exert some significant influences on corrosion risks and their mitigation. For example, marine corrosion is a well documented phenomenon, but the transference of designs from one global region to another requires that many items have to be reappraised for higher ambient temperatures and salinities in order, for example, to avoid crevice and pitting corrosion of stainless materials. Also, given the dependence of atmospheric corrosion upon temperature, relative humidity, rainfall and the presence or otherwise of pollutants, the location of equipment to avoid particularly damaging microclimates can provide significant mitigation of atmospheric corrosion risks. Of particular significance in this respect are the directions of prevailing winds and/or river/sea currents in relation to potential sources of pollutants. For example, in coastal locations, off-shore winds are preferable to on-shore winds and at any location it is preferable to be up-wind/stream rather than down-wind/stream of emissions from cooling towers, stacks and outflows.

Much more control is potentially exercisable at the design stage over the shape of equipment and this can provide significant mitigation of specific corrosion risks, particularly those that arise from poor drainage, the creation of crevices, the disturbance of flow in fluid transport and the condition of surfaces prior to coating:

1. The entrapment of fluids in equipment that is unable to drain completely results in corrosion risks that are usually mitigated readily by simple changes in shape, in some cases by the simple introduction of drainage holes. Some examples of good and bad design relating to the fabrication of steel sections and the drainage of tanks are shown schematically in [Figure 10](#).
2. Crevices and their associated corrosion risks are to some extent inherent in components of complex shape but it is possible to control their severity or even eliminate them altogether by appropriate design and fabrication practices. Some examples of good and bad practices relating to flanged joints in piping systems are shown schematically in [Figure 11](#). Evidently, crevices are inherent to the uses of threaded, or so-called socket-weld, flanges that present open crevices to the process fluid. In principle, the crevice can be removed in the case of the slip-on flange by seal welding the bore as depicted in [Figure 11](#), but the best design is the so-called weld neck flange in which the flange is attached to the pipe with a butt weld, thereby eliminating the crevice. [Figure 11](#) also illustrates how the use of undersized gaskets can create crevices in flanged joints that are eliminated by specifying gaskets of the correct size. Another classic source of crevices in process equipment is the ubiquitous tube/tube-plate joint in the shell and tube heat exchanger. Joints are conventionally fabricated by seal welding the tube into the tube-plate as depicted in [Figure 12](#), followed by expansion of the tube onto the walls of the drilled hole in the tube-plate to reduce the severity of the crevice between them. However, as [Figure 12](#) illustrates, it is virtually impossible to eliminate the crevice, and there remains a residual risk in fluids that are inherently prone to promote crevice corrosion, or where high heat fluxes into the crevice can create such fluids by superheating and concentrating the crevice liquor relative to the benign bulk fluid. In such cases, consideration might be given in design to locating fluids that might promote crevice corrosion on the tube-side of the exchanger. If this is impractical, the crevice can be eliminated, in principle, by back face bore welding of the tube/tube-plate joint, as depicted in [Figure 12](#). However, this is an expensive, difficult procedure and residual risks are more usually mitigated by upgrading the tube and tube-plate materials. In compact heat exchangers in which thin plates or ligaments are

**Figure 10** Examples of bad and good practices in avoiding the entrapment of fluids in structural steelwork and tanks. Adapted from Pludek, V. R. *Design and Corrosion Control*; Wiley: New York, 1976.

separated with very large areas of compression or welded joints, upgrading the material provides the only practical mitigation of crevice corrosion risks. Crevice corrosion risks can also arise at welds where lack of sidewall fusion or root penetration creates a crevice, and appropriate fabrication and inspection procedures must be implemented to prevent such defects.

- Flow disturbance is a common source of local erosion–corrosion problems and it is avoidable by the appropriate design and fabrication of fluid transport systems. In many cases, the basis for designing against erosion–corrosion is the specification of limiting velocities for fluids that have been established by testing and/or experience as in the cases, for example, of cupronickel alloys in seawater<sup>15</sup> and carbon/stainless steels in concentrated sulfuric acid.<sup>16</sup>

However, geometric features of fluid systems can disturb and introduce local turbulences into flows as depicted in **Figure 13** that illustrates schematically how protuberances, cavities, and abrupt changes in direction and cross section can all disturb streamline flows to introduce local turbulences and associated

erosion–corrosion risks. Hydrodynamic considerations show that under typical attached turbulent flow conditions:

$$\tau_w = f/2\rho V^2$$

$\tau_w$  is the shear stress (Pa);  $f$ , the fluid to wall friction factor;  $\rho$ , the fluid density ( $\text{kg m}^{-3}$ ); and  $V$  is the pipe average velocity ( $\text{m s}^{-1}$ ).

The corrosion rate (CR) can be shown to be proportional to  $\tau^{1/2}$  and it thus follows that:

$$\text{CR} \propto (f/2)^{1/2} \rho^{1/2} V$$

An erosional velocity,  $V_e$ , may be defined:

$$V_e = C\rho^{1/2}$$

The constant  $C$  is a combination of fluid corrosivity, fluid to wall friction factor, material properties/chemistry (film strength), and pipe wall surface roughness. This is the basis for the arbitrary erosional velocity in API RP 14E<sup>17</sup> for multiphase fluids in oil/gas production, where  $C$  values of 100 indicate a shear stress range of 75–90 Pa. Once the flow becomes detached/separated as with multiphase slugging flow or down stream of flow disturbances, typified by those shown in **Figure 13**, the corrosion rate is

**Figure 11** Examples of good and bad practices relating to the avoidance of crevices in flanged joints in piping systems.

**Figure 12** Fabrication practices that (a) reduce and (b) eliminate crevices in tube/tube-plate joints in tubular heat exchangers.

controlled by the turbulence intensity and is then proportional to the root mean square value of the shear stress,  $\tau_{\text{rms}}$ . Many of these risks can be mitigated by good design and fabrication practices. Thus, it may be important in specific material/fluid combinations

to use long radius bends/elbows and gradual changes in cross section in piping systems. Correct alignment of joints is important and gaskets or welds should be neither recessed nor protruding into the flow, either of which can introduce damaging flow disturbance.

Components that inevitably disturb flows, such as probes, valves, and orifice plates should be selected, sized, and located to minimize local and downstream turbulence. Thus, straight-through types of valve such as gate, butterfly, or plug valves disturb flows less than throttling, globe, and angle valves, and venturi tubes are preferable to orifice plates, as shown schematically in **Figure 14**. It is also good design practice to separate individual flow disturbers to prevent synergistic effects. For example, it is bad practice to locate an orifice plate or a control valve immediately upstream of a bend and much better

**Figure 13** Effects of (a) protuberances, (b) cavities and abrupt changes in (c) direction and (d) cross section in disturbing streamline flows to introduce local turbulences and associated erosion–corrosion risks. Adapted from Pludek, V. R. *Design and Corrosion Control*; Wiley: New York, 1976.

**Figure 14** Flows are disturbed less by (a) venturi tubes than (b) orifice plates. Adapted from Pludek, V. R. *Design and Corrosion Control*; Wiley: New York, 1976.

practice to locate it at a significant distance upstream or even downstream of the bend as shown schematically in **Figure 15**.

4. Surface condition can influence vulnerability to some forms of localized corrosion. It is particularly significant in relation to the effectiveness coatings that may be used to mitigate corrosion risk for which cleanliness and surface profile are typically specified using internationally recognized standards<sup>18</sup> for blast cleaning to white metal (SA3) and near white metal (SA 2½) as described in more detail in the chapters relating to coatings in this volume. Also important are good shapes and contours and removal of weld spatter, as illustrated in **Figure 16**, all of which should be specified for components that are to be coated.

#### 4.33.7 Mitigation of Galvanic Compatibility Risks

Inevitably, equipment and components are constructed in a variety of materials, and the potential for galvanic interactions needs to be addressed in the design. Although the risk of galvanic corrosion is confined mostly to mixed metal systems, specific ceramic materials such as carbon, graphite and silicon carbide that are used, for example, in heat exchange and jointing systems, have electrical conductivities that are high enough for their potential contributions to galvanic corrosion to require evaluation. Corrosion risk evaluations should address components exposed to external and internal environments, including where moisture films can arise from leaks, splashes or condensation such as at fastenings and welds and electrical earth bonding straps that are bolted, brazed, or welded to structural elements since lack of electrical continuity can have significant safety/instrumentation implications.

The various, published galvanic series of materials have been obtained in specific environments, mostly seawater, and are of limited use in assessing galvanic corrosion risks in other fluids that may have very different conductivities, tendencies to promote passivity on specific materials, etc. However, as a general rule, it is good design practice to avoid material combinations that are widely separated in such series, and in particular to avoid unfavorable area ratios involving small areas of active, anodic material such as fasteners or weld filler metals coupled to larger areas of noble, cathodic material.

**Figure 15** Locating orifice plates and other flow disturbers too close to bends, as in (a), introduces additional risks that are mitigated by (b) downstream, or distant upstream locations. Adapted from Pludek, V. R. *Design and Corrosion Control*; Wiley: New York, 1976.

**Figure 16** Effective coating requires (a) smooth shapes and contours and (b) removal of weld spatter. Adapted from Pludek, V. R. *Design and Corrosion Control*; Wiley: New York, 1976.

Where combinations of materials that present galvanic corrosion risks are unavoidable, mitigation is provided by:

1. Isolation with dielectric sleeves and washers, as shown schematically in Figure 17. Where mitigation is dependent on electrical isolation, this may be frustrated by remote earthing through steel supports, pipe hangers, etc.

**Figure 17** Elimination of galvanic interactions in fasteners by (a) electrical isolation and (b) encapsulation. Adapted from Pludek, V. R. *Design and Corrosion Control*; Wiley: New York, 1976.

2. Encapsulation to exclude the environment, as shown schematically in Figure 17.
3. Coating, preferably of both couple members. If only one can be coated, it should be the noble, cathodic member.

4. Physical separation of couple members to attenuate galvanic interactions, such as at material breaks in piping systems where risks can be mitigated by using insulated spool pieces of appropriate length made from fiber reinforced plastic, or a coated, more noble couple member, as illustrated in Figure 18.
5. Cathodic protection, application of which overrides the spontaneous couple interactions providing protection to both, as in the protection by sacrificial anodes of the steel water boxes of sea-water coolers that would otherwise corrode rapidly due to galvanic coupling with the more noble tube materials.

**Figure 18** Corrosion rate of carbon steel in seawater at a pipe junction with 6% Mo stainless steel as a function of the length of an intervening, insulating spool piece, adapted from Francis, R. *Galvanic Corrosion: A Practical Guide for Engineers*; NACE International: Houston, TX, 2000.

Francis's book is an excellent source of guidance on good practice for the mitigation of galvanic compatibility risks.<sup>19</sup>

#### 4.33.8 Management of Corrosion Risks within the Design Process

The previous sections have reviewed the major inputs/outputs needed to mitigate corrosion risks through attention to detailed thermomechanical and process design issues that may otherwise introduce uncertainty and consequential costs to a project. However, further risks arise from poor control of the management of the design process itself, in particular the effectiveness with which corrosion risks are addressed and appropriate mitigation procedures are implemented within the project design team.

Corrosion management processes and systems are reviewed in a separate chapter in this volume. In keeping with any management process, corrosion management relies on a series of steps using suitable systems, tools and teams, based on standard, international systems for quality, risk, and safety management, as summarized in Figure 19. Various tools are available for specific project stages, such as corrosion risk assessments, corrosion mitigation tactics, and regular formal reviews/audits of corrosion mitigation and management systems. Appropriately staffed, multidisciplinary corrosion teams need to be established and performance indicators adopted that have been developed to ensure that actions are carried out as recommended.

**Figure 19** The corrosion management process.

A corrosion management system should operate simultaneously at various levels, and include:

1. An overall management structure, process, and policy to deal with corrosion issues.
2. Procedures and documentation for engineers and managers with responsibility for corrosion as part of the corrosion strategy or plan.
3. Specification and use of clearly defined tactics based on proven corrosion mitigation practices.
4. Provision of means for the collection and assessment of equipment inspection and monitoring data as part of the operating, maintenance and safety procedures.
5. A system to audit corrosion related activities on a regular basis.

The management of corrosion risk mitigation during the design, procurement, and construction phases of a project requires a formal system that includes measurement and monitoring of the performance of the corrosion management aspects of the overall design system by defining:

1. The objectives of the corrosion control program, be it to reduce risks and/or costs, to promote life enhancement, to define end-of-life strategies, or whatever.
2. Nominated responsibility and accountability for the various components of the program.
3. External sources of acceptable corrosion data, its interpretation to provide trends, and the location and format of a corrosion database.
4. When corrective actions should be implemented, and who is responsible for actions on a day-to-day basis.
5. The duration of the program and when it will be updated.
6. A management-of-change procedure.

This leads to an obvious need for suitable organizational and reporting systems, operating through appropriate documentation and database systems, which provide evidence, for example, that:

1. design engineers are aware of potential corrosion risks associated with the proposed design;
2. advice has been obtained from qualified corrosion specialists where appropriate;
3. suitable corrosion control procedures have been introduced at an early stage in the design;
4. corrosion appraisals have taken place throughout the design process;
5. two or more of the appraisals during design are formal corrosion audits, the first to be undertaken

towards the end of the conceptual/early design stage and the second towards the end of the engineering design/detailing stage;

6. hold points for corrosion audits are introduced into quality plans at critical stages of design, manufacture, construction, installation, or application;
7. guidelines, specifications, and QA/QC procedures are available for the construction, operation, and maintenance phases;
8. plant and equipment items, including units and components, supplied by subcontractors have been subjected to appraisals and audits similar to those carried out for the major plant and equipment items.

In order to ensure that such systems perform effectively, they need to be reviewed and formally audited on a regular basis.<sup>20,21</sup> Performance should be assessed against agreed key performance indicators (KPIs), which for the corrosion team leader during the design process, might typically include:

1. ensuring that cost effective corrosion control is employed;
2. ensuring that appropriate corrosion risk assessments and sensitivity studies are conducted;
3. reviewing all corrosion related documentation;
4. reviewing corrosion related records to assess conformance and reporting out of compliance when necessary;
5. tracking specific procedures and processes to ensure compliance include competency of responsible individuals, departments and organizations and correct implementation, reporting and reaction;
6. ensuring that changes are implemented and incorporated into corrosion-relevant procedures and processes;
7. ensuring that new materials and corrosion control methods are evaluated.

The development and use of performance measurement/KPIs together with the use of regular reviews and audits of the corrosion management system using a formal and transparent framework should ensure that the management of corrosion risk mitigation becomes an integral and effective part of the overall design process.

In the conceptual and early design stages of a project the role of the design team involves:

1. assessment of the technical brief and initial engineering concept;
2. control of costs/budgets within overall economic constraints;

3. production of a technical solution for the project;
4. control of safety, health and environmental (SHE) risks within acceptable limit boundaries;
5. incorporation of corrosion mitigation to deliver the required equipment life.

Risk-based methods are now used routinely to evaluate financial and engineering uncertainties at this stage and are also applied to the evaluation of corrosion risks. They are iterative processes using well-defined steps to support decision-making by providing greater insight into risks and their consequences. They can be used not only to identify undesired and/or unexpected outcomes but also to assess opportunities provided by novel or modified designs. In the conceptual and early design stages, corrosion appraisals would typically include:

1. proposed design and type of construction of equipment items;
2. environments – internal and external, transient and steady state;
3. likely materials;
4. significant corrosion risks and associated SHE and/or financial consequences;
5. proposed corrosion risk mitigation strategies such as protective coatings, corrosion inhibition and anodic or cathodic protection.

The assessment of environments and selection of likely materials are described in the separate chapter on materials selection for corrosion resistance in this volume. Corrosion risks to equipment items would normally be assessed using a qualitative risk analysis (Level 1) that provides a simple ranking of equipment or, in the case of items at higher risk from corrosion, a more rigorous evaluation using a semiquantitative risk analysis (Level 2), a more accurate prioritization that retains vital inputs of a Level 3 analysis but with simplifying assumptions. Only at a later design stage or with highly critical items would a quantitative corrosion risk analysis (Level 3) be employed, which is an in-depth study including assessment of reliability, financial and limited environmental issues. Level 2/3 corrosion risk assessments often employ a risk matrix approach where the likelihood of corrosion is compared against the consequences. In the case of complex installations such as chemical and petrochemical plant, where risk-based inspection is to be employed in service, the assessment of equipment at this stage provides the basis for the initial specification of inspection intervals for equipment.

One of the tools used routinely and effectively in design projects is a series of hold points where key risks and their mitigation are addressed and reviewed/audited by appropriate procedures, as in the case of HAZOP studies of SHE issues in the process industries, or in third-party reviews of major civil engineering designs. The aim is to manage not only technical issues and ensure compliance with codes and standards but also to manage human responses and actions such as ensuring that any changes are checked and approved by suitably experienced specialists as part of a management of change procedure. These overarching risk management procedures are very effective vehicles for the management of corrosion risks and their mitigation.

At the engineering design/detailing stages, corrosion risks rarely arise from inadequate basic design or initial materials selection, but from deficiencies in the detailed design or poor provision of information for certain aspects of the construction, operation and maintenance of the equipment. These are essentially quality control issues that should also be addressed by appropriate reviews/audits of the design. Data sheets and drawings are best addressed with checklists that cover the detailed issues summarized in [Figure 2](#). The compilation of such lists will depend on the industry and the type of project. For example, API 570<sup>22</sup> is a qualitative risk analysis approach used in the petroleum industry for guidance on areas/locations subject to corrosion damage and the need for inspection. It also identifies specific features that are susceptible to high rates of corrosion attack or cracking which require attention during design such as injection points, deadlegs, surfaces beneath insulation, linings and deposits, etc. Another publication<sup>21</sup> compiled by the UK offshore oil/gas industry addresses the impact of corrosion on integrity issues in existing facilities, in particular the management of external marine corrosion on support structures, walkways, cable trays, etc. and it provides many illustrations of typical damage which are instructive to designers of new facilities.

Sufficient information must be provided in the final specifications and drawings to enable the development of plans for construction, fabrication and manufacture of all items and components. The final reviews/audits of the detailed engineering design may require modifications or revisions and should anticipate that corrosion control in completed facilities can be adversely affected by poor workmanship and site damage. These effects can be

minimized by correct supervision and inspection based on frequent QA/QC reviews of all aspects of construction and commissioning as part of the design. These checks and inspections should be specified in the final design as to be carried out on a regular basis as part of organized appraisals and must include agreed reporting procedures and means of implementing corrective actions to minimize future problems.

It is important that recommendations and specifications with regard to corrosion mitigation should not be negated during the construction phase of a project. The contractor typically undertakes procurement of construction materials and equipment, vendor assessment and commissioning of associated plants. The detailed design stage corrosion audit should have already addressed those aspects associated with required reliability, maintainability and ease of construction as prescribed in detail in the contract documents and specifications. The aim should be to ensure that procedures used during manufacture and construction do not jeopardize the longer term corrosion control requirements of the design. The overall priority must be with the project life cycle and associated SHE issues and not with minimizing construction time or costs. Some typical examples of such issues are as follows:

1. The shape of items should not be changed in a manner that might reintroduce corrosion risks.
2. Installed pipework should be self-cleansing to prevent deposit build-up (minimum velocity) and self draining to prevent pooling during shutdown.
3. Bend radii, changes of section, etc. should be as per design to mitigate erosion corrosion risks.
4. Specified impingement/wear plates should be installed.
5. Adequate access for inspection and maintenance should be provided.
6. Chemical cleaning and passivation procedures should be undertaken in strict compliance with specification.
7. Shapes, contours, surface preparation, and cleaning should be as per specification on surfaces that are to be coated.
8. Weld spatter should be removed and weld protrusions ground to specification.

In conclusion, problems often occur in operation because of failure to apply good management practices during the design process to the deployment of good technical practices, many of which have been codified in industry standards, recommended practices and guidelines. The corrosion management

practices described in this section should do much to improve the deployment of resources to achieve project design objectives and the implementation of specific solutions to maximize the effectiveness of corrosion mitigation tactics.

### 4.34.1 Introduction

Until fairly recently, the structural integrity of most engineered structures has been assured by two factors:

- Design in accordance with codes or rules incorporating empirical safety factors.
- In-service inspection to provide assurance that no accidental or unanticipated damage has occurred.

However, it is only prudent to accept that operational loads may vary beyond design levels, and material degradation may be greater than anticipated. The safety factors used at the design stage may not, therefore, guarantee through-life structural integrity. Hence, periodic inspection is also carried out to determine the actual levels of damage, and to check the adequacy of the design loads and resistance values.

There is a widely held view that prior to the emergence of risk-based inspection (RBI) as a process for planning inspections, specifically of pressure containing equipment, all inspection activity was conducted on a time basis, that is, at regular set intervals. These intervals would vary according to the type of equipment, its service, and any specific national regulations that applied. This, of course, is generally not entirely true!

RBI has been practiced by engineers responsible for integrity management since the very first time an inspection budget, or the time allowed for inspection, did not cover the entire plant. Engineers were forced into a position where they had to decide between inspecting one thing or another. In almost all cases, that decision would be made on the basis of a perceived risk. In this case, the specific risk of concern is that of loss of integrity due to structural failure. RBI as we know it today is a means of formalizing that decision process such that it becomes consistent, transparent, and fully auditable.

Both design and inspection strategies must take account of the risk of structural failure: that is, both the probability of failure and its consequences need to be considered. Using traditional approaches to inspection planning, risk tends only to be considered implicitly and is not quantified in an auditable manner. There is thus real concern that high-risk and low-risk areas will not be clearly identified. This may then mean that low-risk areas are inspected to an excessively high level (leading to needlessly high inspection costs), while high-risk areas may not all be afforded sufficient attention and priority. Without the explicit and rigorous consideration of risk, it may not therefore be possible to demonstrate that the structural integrity of the plant has been satisfactorily characterized.

An inspection strategy based on risk avoids the inadequacies of the traditional approach. The concept of risk takes into account, not only the probability, but also the consequences of structural failure. These may encompass consequences in terms of lost profits, repair and compliance costs, human casualties, and environmental clean up costs. Such a strategy

ensures that inspection effort is targeted appropriately to optimize costs and benefits, and provides an auditable demonstration that this has been done with due diligence.

With such an emergent technology, there are many ways in which the objectives can be achieved. The methods available vary in cost, quality, and detail and operators can experience difficulty in selecting a methodology which is fit-for-purpose. This review aims to summarize the concepts, technology, and currently available approaches and the advantages and disadvantages of each.

#### 4.34.1.1 What is Risk?

In order to be clear about what RBI really is, it is first necessary to gain an understanding about what 'risk' is in this context. The term is used in common parlance to describe a range of features of a real or postulated event. For example, 'risk' may be used to indicate the likelihood of an event or perhaps even to describe the consequences of the same event. If used correctly the term should describe both. The situation is further complicated by the use of the term 'hazard' as applied in hazard and operability studies (HAZOPs). 'Hazard' and 'risk' are used interchangeably in everyday vocabulary.

The UK Health & Safety Executive has sought to make a conceptual distinction between a 'hazard' and a 'risk' by describing a 'hazard' as<sup>1</sup>

the potential for harm arising from an intrinsic property or disposition of something to cause detriment

and 'risk' as

the chance that someone or something that is valued will be adversely affected in a stipulated way by the hazard.

Accepting this distinction it follows that risk in the context of RBI is the product of the chances and consequences of a structural failure. It also follows that the management of risk in this context has three components:

- hazards must be identified;
- risks they give rise to should be assessed;
- appropriate control measures should be introduced to address the risks.

Additionally, and because of the way in which we define risk, it is both convenient and commonplace to divide risk into three categories:

- safety risk, that is, risks to people's lives and health;
- environmental risk, that is, risk to the environment, for example, pollution, effects on marine life, etc.;
- business or economic risk, that is, risk of lost production/revenue.

These are all the things that we value and could be affected adversely if structural failure occurred.

#### 4.34.1.2 Who is Responsible for the Management of Risk?

The public accepts that we need to continue to operate hazardous plant and equipment in order to manufacture products which are a vital part of modern life, for example, gasoline, diesel, plastics, pharmaceuticals, etc. However, as part of their review of this subject within the United Kingdom,<sup>1</sup> the Health & Safety Executive observed that this acceptance is moderated by expectations that:

- those responsible for the hazards should ensure that adequate measures are taken to protect people from the harmful consequences that may arise from such hazards; and
- the State should be proactive in ensuring that its arrangements for securing the protection of people from risks are adequate and up to date as distinct from reacting to events; and that those arrangements should address, as necessary, the concerns to which the hazards give rise.

This clearly puts responsibility for management of risks into the hands of organizations who own and operate hazardous installations. It is this line of thinking that has led many parts of the world to the conclusion that regulations need to reflect responsibility for risk management. As such, there has been a move away from prescriptive time-based inspection (inspection being a risk management activity) to inspections based on an understanding of the level of risk represented by each part of any hazardous installation.

#### 4.34.1.3 The Structure of a Risk Management Program

The UK Health & Safety Executive's report on how it comes to decisions on risks<sup>1</sup> outlines six stages in the decision-making process:

- deciding whether the issue is primarily one that can impact safety and health;
- defining and characterizing the issue;

- examining options available for addressing the issue, and their merits;
- adopting a particular course of action for addressing the issue efficiently and in good time, informed by the findings of the second and third points above and in the expectation that as far as possible it will be supported by stakeholders;
- implementing the decisions;
- evaluating effectiveness of actions taken and revisiting decisions and their implementation if necessary.

Figure 1<sup>2</sup> illustrates the process of RBI.

It is clear from Figure 1 that an RBI process encompasses all the aspects of a risk management program as defined above. The focus of risk management is also clear, that is, asset integrity.

#### 4.34.1.4 The Role of RBI in Asset Integrity Management

Hazard management of large industrial facilities is a complex process which is active at each of the six key stages in the asset life-cycle (i.e., design, construction and hook-up, commissioning, operation, modification, and decommissioning).<sup>3</sup> The primary process in hazard management is considered to be asset integrity assurance.

Asset integrity management (AIM) of a large industrial facility encompasses three essential elements, as shown in Figure 2.

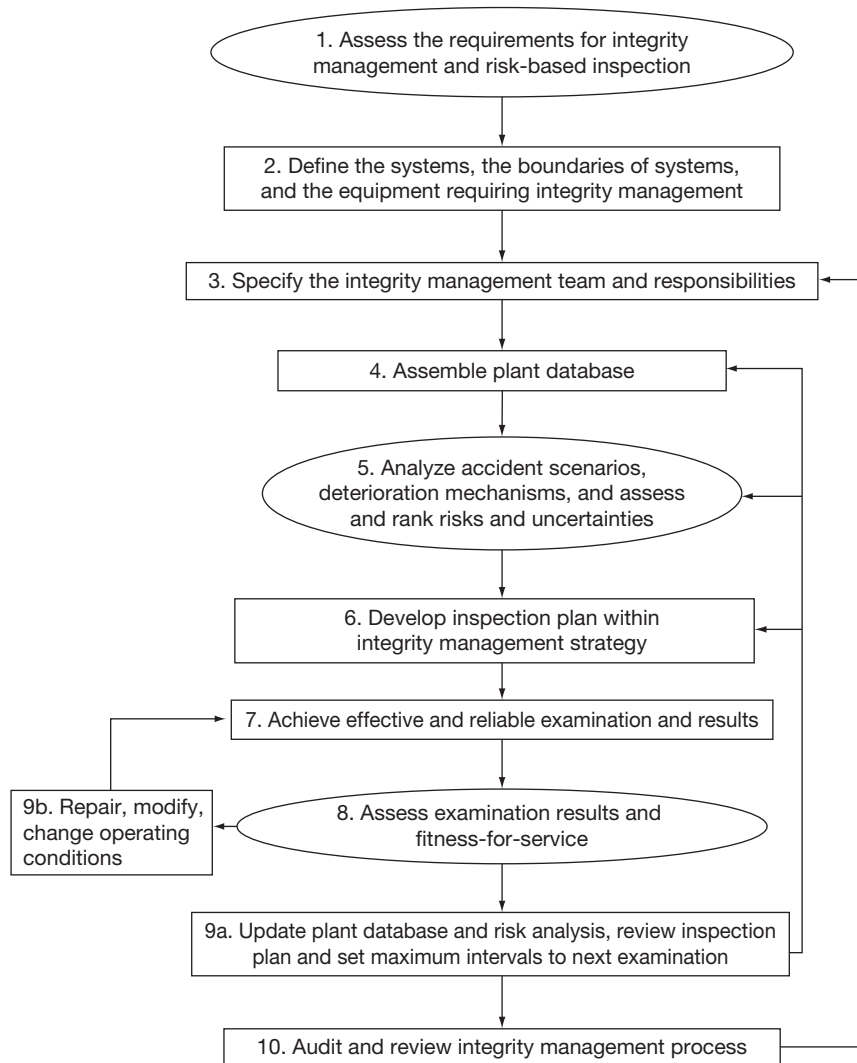

These elements may be defined as follows:

*Mechanical integrity* is the ability of the asset to withstand the design loadings (i.e., design pressure/stress, design temperature, etc.). It is primarily concerned with structural integrity, pressure containment, and leak tightness, and focuses on pressurized equipment, piping systems, and major structures.

*Functional integrity* is the ability of the asset to perform its required function effectively and safely. It is primarily concerned with the reliability of safety critical elements such as emergency shutdown systems, critical process control systems, and hazard mitigation systems (e.g., gas/fire detection systems, fire fighting systems, etc.).

*Operational integrity* is the ability of the asset personnel to operate the facility safely and effectively. It is primarily concerned with human factors such as competency, management systems, reporting systems, anomaly management, etc.

Several risk-based methods are employed in hazard management of large complex plants. RBI is the use of risk assessment to formulate and prioritize inspections

**Figure 1** Risk-based inspection (RBI) process.

of pressure vessels, piping systems, and pressure safety valves. Its primary concern is mechanical integrity. **Figure 3** shows the role of RBI within a typical AIM system for an oil and gas production facility.

#### 4.34.1.5 Types of Risk Assessment

Risk assessment methodologies may be defined in terms of the nature of the assessment performed. Three terms in common usage are qualitative, semi-quantitative, and quantitative risk assessment.

These three assessment techniques are broadly aligned with three different strategies in the performance of risk evaluation, which include expert judgment, rule-based analysis, and quantitative calculation.

##### 4.34.1.5.1 Qualitative RBI

Qualitative RBI is based on the results from a qualitative risk assessment, which is usually executed through expert judgment. Normally this would employ an expert, multidisciplinary team, with representatives from all relevant engineering disciplines, including materials/corrosion, mechanical, process, operations, maintenance, and safety engineering. Risk assessment would be performed through discussion, with the team agreeing on the likelihood of failure and the resulting consequence.

Expert judgment can be the result of informal or formal processes.<sup>4</sup> It is necessary to distinguish between formal, expert judgment and informal expert judgment processes – the latter being the way expert judgment has traditionally been used during RBI

assessments. Expert judgment has been used in analysis and assessments in informal ways, through the expert's implicit and undocumented reasoning, inferences, and scientific knowledge.

The advantages of this risk assessment technique are that it is relatively easy to perform and can incorporate lessons from the plant experience gained by experts present on the team.

More recent formal uses of expert judgment exist that are explicit, structured, and well documented. They aim to bring out assumptions and reasoning that are at the base of a judgment, to quantify and document it so that others can appraise it. Although

formal judgment can be resource consuming (in terms of cost and time) and appear less flexible and creative than informal judgment, it brings out a deeper understanding of the issues, drawing out diverse opinions. This can reveal areas of disagreement or agreement with increased possibility of a solution. Furthermore, formal judgment gives access to all aspects of the analysis (assumptions, models, data, expert's thinking) and provides the possibility for others to review the process of judgment.<sup>4</sup> One UK HSE study that examined RBI in practice<sup>5</sup> found a lack of transparency in parts of the RBI decision making process indicative of informal expert judgment. It seems therefore that the natural development of qualitative RBI assessment will be to move to a formalized expert judgment method in the future.

The main disadvantages of the technique in both its informal and formal modes are inconsistency (less so for formal expert judgment), cost, and speed. As each item needs to be discussed in detail, assessments are never rapid and this has the effect of pushing up costs simply because of the consumption of large volumes of expert's time. It should also be noted that the next time the RBI team is assembled in order to conduct the review process, any change to the team line-up introduces another element of variability that can affect the outcome of the assessment.

#### 4.34.1.5.2 Quantitative RBI

Quantitative RBI is based upon a quantitative risk assessment. It results in fully quantified absolute failure probabilities and consequences specific to the

Figure 2 Essential elements in AIM.

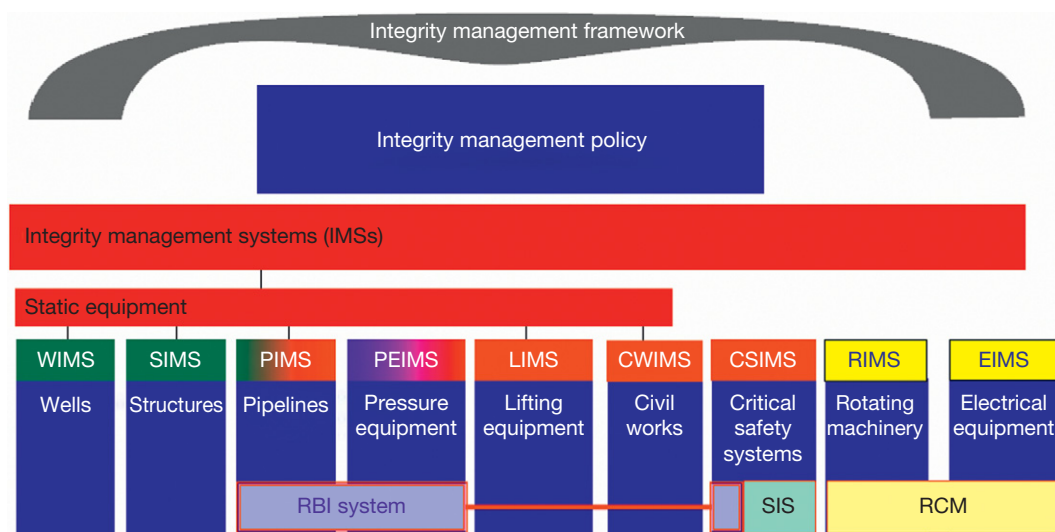

Figure 3 The RBI in the asset integrity framework.

item under consideration and using only the attributes of that specific item.

Robust consequence of failure calculations should consider the influence of each chemical constituent of each process fluid. The assessment should model the dispersion of each chemical constituent, and assess its contribution to failure scenarios such as explosion, flash fire, pool fire, toxic release, over-pressurization, pollution, etc.

Robust likelihood of failure calculations should include accurate predictive, often probabilistic modeling of all damage mechanisms, regardless of their 'perceived' likelihood.

The advantage of the quantitative method of risk assessment is accuracy; the major disadvantage is that the process is extremely slow and has extremely challenging data requirements.

There are a number of reportedly 'quantitative' methodologies available, including the API level III assessment.<sup>6</sup> However, all these techniques fall short of a truly fully quantitative assessment. First, they normally rationalize the process fluid into a 'representative fluid' which, necessarily, does not represent all chemical constituents present. For instance, API 581 allows for 17 different representative fluids,<sup>7</sup> which includes C<sub>9</sub>–C<sub>12</sub>, C<sub>13</sub>–C<sub>16</sub>, C<sub>17</sub>–C<sub>25</sub>, H<sub>2</sub>, and H<sub>2</sub>S as separate 'representative fluids', but never considers combinations of the same. Clearly, this could be a significant limitation. For example, in a refinery hydroprocessor plant, where the process stream consists of 50% H<sub>2</sub>, with the balance being hydrocarbons and H<sub>2</sub>S, the calculations would only quantify 50% of the actual release.

Secondly, many 'fully quantitative' techniques only quantify damage mechanisms that are selected for assessment in a preassessment phase, which is normally qualitative in nature. Thus, the assessment is selectively quantitative, rather than fully quantitative, and is reliant upon the expert correctly identifying appropriate damage mechanisms to assess.

#### 4.34.1.5.3 Semiquantitative RBI

Semiquantitative RBI employs simplified quantitative assessment models to derive pragmatic risk ranking for components within a pressure system. It should be noted that the term 'semiquantitative' refers to an assessment methodology that seeks to quantify all deterioration mechanisms and consequence scenarios, albeit in a simplified manner that requires less data than a fully quantitative methodology. Semiquantitative RBI does not include systems which quantify some aspects and use qualitative judgment for other aspects.

#### 4.34.1.6 The Matrix

At this point in the review, having just discussed the qualitative, semiquantitative, and quantitative methods of assessment, it is appropriate to examine the means by which the results of the risk assessment phase of an RBI study are presented, that is, the risk matrix.

The matrix has been the cause of much debate since RBI was first used. Questions of what size it should be, that is,  $3 \times 3$ ,  $4 \times 4$ ,  $4 \times 5$ ,  $5 \times 5$ , and whether or not it should be 'skewed' are often the subject of discussion.

The answers to these questions are intrinsically linked to two features of RBI:

- which methodology you choose;
- the data with which you have to work.

First, consider fully quantitative RBI. **Figure 4** presents the type of results you might expect to generate.

Each red dot represents an individual assessment for a uniquely identifiable item of equipment or piping. Three regions are clearly marked.

- *Acceptable*: The evaluated risks are acceptable.
- *ALARP*: The identified risks should be maintained as low as reasonably practicable. These risks need active risk management, for example, inspections, monitoring, maintenance, etc.
- *Unacceptable*: These risks cannot be tolerated. The owner of the risk should either introduce engineered mitigations or redesign the equipment to mitigate the risk.

Failure probability is expressed as a number between zero and one and is often the result of very detailed probabilistic assessment taking into account details of the various potential failure modes and the

**Figure 4** Illustration of results from a quantitative RBI study.

material/structural response at every stage of the degradation process. Failure consequences are often expressed in currency terms but may also include expected number of fatalities or injuries caused by a failure. Full dispersion, blast and fire modeling are required, together with financial modeling and environmental impact assessment for every postulated failure.

The amount and quality of data required to conduct this type of assessment is prohibitive in terms of normal budgets available. The solution to this problem is to apply an approximation to the fully quantitative methodology. The approximation is the matrix approach. **Figure 5** illustrates the concept of a matrix superimposed on fully quantitative results. In this case, a simple  $3 \times 3$  matrix is shown.

It is immediately apparent that the matrix approach seeks to define broad bands of failure probability and consequences into which individual risks can be assigned. This can be done qualitatively by expert judgment as discussed above, by simply assigning a high, medium, or low score to each identified risk. Alternatively, rules can be used to assign the categories in a semiquantitative manner.

The  $3 \times 3$  matrix has a couple of significant disadvantages.

- The resolution is not sufficient to deliver improvements in inspection planning that can be achieved by using narrower bands, that is, the bands are too wide to distinguish between equipment that may need inspection every 10 years and that which requires it every 5 years. This, for a large inventory of equipment, can have a major impact on inspection costs.
- It is difficult to justify 'skewing' a  $3 \times 3$  matrix. Often, these matrices are skewed to reflect the understandable desire to inspect equipment with high consequences of failure even if the probability is low.

**Figure 5**  $3 \times 3$  risk matrix.

Since the publication of API 580 and 581 it has been normal to consider the use of a  $5 \times 5$  matrix as shown in **Figure 6**.

This dimension of matrix has a number of advantages.

- The resolution is as high as reasonably possible for the use of expert judgment allowing qualitative RBI to be chosen if appropriate.
- The number of bands is sufficient, but not too many, to allow sensible construction of rules for semiquantitative analysis using commonly available data, that is, that from process flow diagrams, piping and instrument diagrams, material selection reports, heat and material balance data, and equipment drawings.
- It is relatively easy to justify a degree of skewing to this matrix. The highest risk level extends to lower failure probabilities to place emphasis on failure consequences. This skewing process also goes some way to mitigating uncertainty inherent in the RBI analysis (qualitative and semiquantitative), particularly in the degree of knowledge or modeling assumptions used to predict failure modes.

There are other variants to the matrix size, for example,  $4 \times 5$  (four levels of failure probability and five of failure consequences), but all are essentially approximations to the fully quantitative approach designed to reach a useful conclusion without prohibitive data requirements. In choosing an approach and/or a matrix size, practitioners should consider the following:

- *Resolution*: will the resolution I am using deliver distinctions that I can use in planning inspections to better target risks within the inspection budget? Can the resolution I want be justified given the data/information I have to do the assessment?
- *Auditability*: can my approach be fully audited, that is, can I justify the decisions made in the process?
- *Uncertainty*: what are the uncertainties in my assessments and where are they? How do I mitigate these uncertainties? Importantly, do any of the uncertainties introduce optimism into the risk assessment?
- *Practicality*: can I conduct the level of assessment I want to with the resources I have?
- *Reproducibility*: if I did the analysis again next week, would I get the same result? If not, why and how can I reduce the effects of this variation?
- *Cost*: what are the real costs of doing this assessment and what benefits can it achieve?
- *Time*: can I complete this assessment in a reasonable timeframe?

**Figure 6** 5 × 5 RBI matrix.

#### 4.34.1.7 Current International Practice

The first point to note when considering international practice of RBI is that there are presently no national or international standards that cover the technology of planning inspections on the basis of risk. There are various standards that cover implementation of inspections on plant, but none of these address the manner in which RBI should be carried out.

Two publications that have gained prominence in RBI are API publication 581<sup>6</sup> and API recommended practice 580.<sup>8</sup> In essence, API RP 580 describes the necessary features of an RBI procedure, providing guidance on development of an RBI program for static equipment and piping in oil and gas industry service. API 581 is somewhat different in that it builds on API RP 580 to produce a methodology which may be followed by anyone wishing to conduct RBI on such equipment. It is not however, a standard that requires 'compliance' in a legal sense.

##### 4.34.1.7.1 API 580 and 581

API 580 was initially developed over 5 years by a group of more than 22 international refining, chemical, and exploration companies.<sup>9</sup> The group comprised mechanical engineers, materials/corrosion engineers,

NDE specialists, and individuals responsible for mechanical integrity and inspection programming on operating plant.

The document is very clear that it is a guidance document and not intended to:

- supplant other practices that have proven satisfactory;
- discourage innovation and originality in inspection;
- be a substitute for the judgment of a responsible, qualified inspector, or engineer; and
- be construed as a code of rules, regulations, or minimum safe practices.

The document is a supplement to other API publications, codes, and standards on plant inspection. It requires RBI assessment to systematically evaluate both failure probability and consequences based on all forms of deterioration that could reasonably be expected to affect equipment in its particular service.

One particularly important element of API 580 is that it sets out what RBI will not do, that is, it will not compensate for:

- inaccurate or missing information required in assessments;

- inadequate design or faults in equipment fabrication or installation;
- operation of equipment outside the acceptable design envelope;
- not effectively executing the inspection plans;
- a lack of qualified personnel or the absence of required disciplines in the assessment process; and
- a lack of sound engineering or operational judgment.

API 580 also requires that RBI assessment should be documented in such a way that it allows recreation and updating of the assessments by people not involved in the original assessment. In other words, the assessments should be fully auditable and justifications are required for all decisions and judgments made.

API 581 is a development of API 580 insofar as it provides a recommended practice for the practical application of the principles described in API 580. It should be noted, however, that API 581 is a 'recommended' practice and does not claim to be the only approach that can satisfactorily achieve the aims set out in API 580. This distinction has given rise to a number of subtly different approaches in common use, many of which are housed in software applications. Virtually all RBI software claims API 580 compliance.<sup>10</sup> Only software produced by API itself is compliant with API 581 in every respect.<sup>10</sup>

#### **4.34.1.7.2 Common practice**

Besides API 581, there are many RBI approaches in common use. Many larger companies have chosen to develop 'in-house' approaches and associated software to achieve consistency across their total assets worldwide. Beyond the larger operators, there are many independent RBI applications available. These vary in cost and quality but all can reasonably claim to be compliant with API 580 as can the company specific approaches.

### **4.34.1.8 Creating the Inspection Plan – Assigning Inspections from Risk Assessment**

#### **4.34.1.8.1 Selection of appropriate inspection techniques**

RBI is ultimately concerned with optimizing inspection activity. Part of this process is the selection of appropriate inspection techniques. In the modern world, there are many new and innovative inspection techniques available, and this complicates the inspection method selection process.

The overriding principle in selection of an inspection technique is that the technique should be able to

detect the type of damage identified by the RBI assessment. This should be a matter of record, that is, the technique should be documented to the extent that it can be shown to be capable of relevant damage detection in a robust and reliable manner when applied in the field under plant conditions.

A second, but essential principle in technique selection is the degree to which the results of the inspection can be quantified. The feedback loop in the RBI process is dependent on information trends to justify increasing or decreasing inspection intervals to match the actual risk. Techniques should be capable of directly capturing trends in data, for example, wall thicknesses or crack dimensions, or be recordable in a systematic manner that allows trends to be inferred, for example, percentage of surface affected by general corrosion. Phrases like 'some corroded areas' or 'OK' are of no use in management of the RBI feedback loop.

#### **4.34.1.8.2 Selecting the interval**

Inspection intervals are related to the risk of failure and their assignment requires full documented justification within the RBI documents for a plant. In many cases 'risk' at this stage is referred to as 'criticality.' Returning to [Figure 6](#) as an example, the various locations on the matrix represent different levels of risk, but the colors of the 'boxes' represent criticality or 'risk rank.' In this case red represents criticality 1 (high), orange is criticality 2 (medium high), yellow is criticality 3 (medium), blue represents criticality 4 (medium low), and green is criticality 5 (low).

For the purposes of inspection, scheduling it is good practice to plan on the basis of damage specific criticality, that is, combination of each identified failure probability (per damage mechanism) with the overall failure consequences for the equipment. This makes sense because individual damage types require different techniques to detect them and will occur at different rates, thereby requiring different intervals. Some rationalization of inspections is possible in most inspection planning exercises but this is normally best handled by detailed planning that also encompasses logistical considerations such as the availability of scaffolding and portable power supplies, etc. These latter considerations are not a part of RBI assessment.

An example of an inspection interval specification is provided in [Table 1](#).

In this example, confidence grade is a measure of the degree of confidence that exists in the predictability of

future integrity performance based on known information. The definition of each grade is broadly based on the definitions given for inspection grades by the Institute of Petroleum.<sup>11,12</sup> These grades reflect confidence in inspection data and anticipated future condition.

- Grade 0 – no relevant inspection history, or rapid confirmed/anticipated degradation, or uncertain process conditions, that is, uncertain present and future condition.
- Grade 1 – at least one recorded relevant inspection but with potential significant degradation, that is, certain present condition, uncertain future condition.
- Grade 2 – at least one satisfactory inspection, that is, certain present and future conditions.
- Grade 3 – more than one satisfactory inspection over a prolonged period of time.

An alternative and in some cases complimentary approach is to schedule inspection based on calculated remnant life for the equipment, adjusted according to the assessed consequences of a failure. Table 2 provides an example of how this can be achieved.

In the example, it is clear that an item of equipment with high consequences of failure and low confidence grade would be inspected on a much shorter timescale (in terms of remnant life) than another item with low failure consequences and high confidence.

**Table 1** Example of inspection interval specification based on damage specific criticality

Damage specific criticality	Confidence grade			
	0	1	2	3
1	12	36	36	36
2	24	36	72	72
3	24	48	72	96
4	36	48	84	120
5	36	48	84	144

**Table 2** Example of fractions of remnant life used to schedule inspections

Consequence level	Confidence grade			
	0	1	2	3
1	0.1	0.13	0.16	0.2
2	0.175	0.23	0.29	0.35
3	0.25	0.33	0.42	0.5
4	0.375	0.5	0.625	0.75
5	0.5	0.67	0.83	1

Most RBI systems, which are in operation utilize concepts such as those above in order to form working RBI plans. The terminology changes, as do the precise values for intervals and life fractions used, but the basic process remains the same.

By combining the risk assessment, the assigned confidence grade, and the selection of a suitable inspection technique, the inspection plan is formed. It is important that the logic for creating the plan is documented because this constitutes a critical part of the audit trail for the whole RBI program.

#### 4.34.1.9 Key Success Factors for RBI

Three distinct parties have an interest in the effectiveness of a RBI program. These may include the RBI practitioner (whether this be an individual or a team within the operating company, or an external consultant), the operating company, and the regulation authority. Each of these parties has a different interest, and hence, each judges successful RBI by different criteria.

##### 4.34.1.9.1 RBI practitioner

The practitioner judges RBI by the ease and speed of application. This requires minimal data and simplified assessment methodologies. Restricting data requirements to that available in common engineering documentation such as process flow diagrams, piping and instrumentation diagrams, piping line lists, and heat and mass balance data normally provides sufficient data for RBI assessments, and is frequently available in electronic format, making data capture very efficient.

Additionally, as the RBI system needs continual feedback from completed inspections, changes in operating parameters and feedstock, the RBI practitioner needs an RBI system that is readily managed. The capture of changes and updating of results need to be simple and efficient.

##### 4.34.1.9.2 Operator

Key success factors for an operating company include an optimized inspection program, with minimal plant down time for scheduled inspections. The inspection regime should maximize plant reliability and eliminate surprise failures or unplanned shutdowns.

In order to achieve this, the RBI system needs robust likelihood of failure models that accurately predict plant behavior. Optimistic likelihood models and assessment techniques, which are liable to

overlook pertinent deterioration models would clearly lead to unpredicted failures, and damage the credibility of the RBI methodology.

On the other hand, overly conservative likelihood models also harm confidence in the RBI system by continuously overestimating the rate of deterioration, leading to unnecessarily onerous and frequent inspections which can overload the operator's resources. In one plant, a simple, qualitative RBI approach to creep damage resulted in the scheduling of frequent inspections for creep damage in 400 pipes in one process unit. After several inspection campaigns, early stage creep was found in only five pipes.<sup>13</sup> Using a more accurate, quantitative likelihood model reduced the number of pipes for which creep damage was credible to 30, which included all five pipes which had experienced early stage creep damage.<sup>11</sup>

Accurate prediction of plant condition allows optimization of inspection driven shutdowns, maximizing the operating period between inspections and optimizing the workload in each shutdown. These models need to be readily and efficiently adaptable to process and feedstock changes, capturing any significant changes, and revising the plant inspection program accordingly.

#### **4.34.1.9.3 Regulating authority**

A study performed on behalf of the UK Health & Safety Executive compared RBI assessments performed by a number of different RBI assessment teams for a specific set of case studies. Results showed inconsistencies between the findings from the various RBI assessment teams,<sup>5</sup> including:

- variation in the damage mechanisms selected for likelihood assessment;
- significant variation in the assessed likelihood of failure between the assessment methodologies;
- significant variation in the type and frequency of inspection; and
- a lack of speculative inspections aimed at confirming the absence of deterioration through damage mechanisms considered unlikely or inactive.

These findings demonstrate the primary concerns of regulatory bodies. Essentially, safety and environmental impact are the primary and secondary concerns, while business impact is of no concern. Consequently, key success factors for RBI include a robust, comprehensive assessment methodology that addresses all safety threats adequately and consistently.

The regulatory authority is often concerned that RBI scheduling may elevate business risks above

safety risks. A robust RBI system should therefore ensure that safety consequences are not diluted in their significance to the overall consequence of failure result by use of an average consequence of failure from individual assessment results that consider safety, business, and environmental impact.

#### **4.34.1.9.4 Summary**

In summary, therefore, the key factors for a successful RBI program that meets the needs and expectations of all parties may be defined as:

- accurate likelihood modeling;
- application of confidence criteria;
- realistic consequence modeling;
- selection of appropriate inspection techniques;
- robust authoritative reviews;
- intelligent interpretation of inspection findings;
- efficient capture of process or hardware modifications;
- speed of application; and
- consistency of results.

#### **4.34.1.9.5 Accurate likelihood modeling**

Accuracy in likelihood modeling includes correct identification of all active deterioration mechanisms, and accurate prediction of the rate of this deterioration.

The identification of all active deterioration mechanisms presents a significant challenge to the RBI assessment. Deterioration may occur under normal operating conditions, which include normal operating fluids, pressures, temperatures, and flow rates. In qualitative RBI systems, and those which employ a qualitative preselection of pertinent damage mechanisms, the selection of likelihood assessment models is critically dependent upon the competence and expertise of the RBI practitioner or expert review team. In other words, the weakness of these systems is that they rely upon human expertise to correctly identify which damage mechanisms are actually assessed. A more robust system is one that considers a comprehensive range of deterioration mechanisms and requires each damage mechanism to be ruled out based on quantitative or semiquantitative calculations.

Following identification of pertinent damage mechanisms, the likelihood assessment requires accurate modeling of the likelihood of failure. For time dependent deterioration mechanisms, such as corrosion, creep, or fatigue, the likelihood assessment should be able to predict a deterioration rate (in the

case of corrosion) or an anticipated life (in the cases of creep and fatigue). For non-time-dependent mechanisms, such as stress corrosion cracking, brittle fracture, etc., calculation of a susceptibility rank is probably the best option.

In either case, accurate modeling of deterioration mechanisms is essential for two reasons. First, an accurate understanding of the likelihood and rate of deterioration is essential for optimization of inspection plan. Overly conservative assessments will lead to specification of an onerous inspection plan both in the number of inspection tasks specified and their frequency. An optimistic assessment will specify too few inspections, with too long an interval between inspections.

Secondly, accurate likelihood modeling is essential to demonstrate the credibility of the RBI system. Confidence in the RBI assessment is gained when the RBI prediction and the actual observed experience are in agreement. Any significant difference between the prediction and the experience demonstrates that susceptibility to failure is not well understood. Accurate prediction of deterioration, rather than a simple reliance on the past measured rate of deterioration, provides better confidence in the integrity of the asset because the prediction can be modified to account for process or operating changes as they occur.

In a simple practical example, an oil and gas terminal experienced failure of a tube bundle after 11 years of operation. The corrosion engineer used the measured corrosion rate from the original bundle to predict the expected life for a like-for-like replacement, concluding that it would give a similar life, which was acceptable. Accurate RBI likelihood assessment (performed by an external consultant after ordering the replacement bundle), told a different story. The terminal had recently brought a new field online. Following the addition of the new field, the exchanger started to operate under wet conditions and the corrosion rate was high. The replacement tube bundle failed within a few months of installation.

#### **4.34.1.9.6 Application of confidence criteria**

A robust RBI system should account for the degree of confidence that can be assumed in any assessment. Confidence should consider the accuracy of the assessment technique, predictability of operating conditions, effectiveness of the inspection technique, and the integrity of the item under consideration.

Some form of confidence index is necessary to address the degree of accuracy of the models used to assess the deterioration rate. Factors to consider are the inherent accuracy of the deterioration model,

its degree of conservatism (e.g., creep calculations and fracture assessments often use very conservative material property data), and the comparison of predicted deterioration rates with actual measured rates.

First, when the deterioration rates experienced in service agree with the predicted deterioration rates, there is good confidence in the assessment technique. However, when the predicted rates differ from the measured deterioration rates it must be concluded that likelihood of failure is not well understood.

Second, deterioration frequently occurs due to process upset conditions, process degradation products, or rogue elements, such as catalyst fines or particulates. As many of these conditions are abnormal or unexpected operating scenarios, they are difficult to anticipate and are readily overlooked. Additionally, failures may occur due to design errors or undetected manufacturing defects. Even the most robust RBI system would be challenged to identify all of these possibilities.

Third, the confidence index should consider the effectiveness of previous inspections. Inspection effectiveness has two aspects; first, the ability of the inspection technique to actually identify and correctly characterize a defect or deterioration rate, and second, the coverage of the technique.

Finally, the confidence index should reflect the confidence in the integrity of the item under consideration. For example, in the case of an item known to be susceptible to high rates of deterioration, with robust inspections showing that the item has suffered significant damage and is close to failure, confidence in the RBI assessment is very high, but confidence in the integrity of the item is very low.

Failures often approximate a 'bath tub' curve (see [Figure 7](#)), where early in the plant life several failures occur due to design errors, undetected manufacturing defects, etc. Following this initial operating period, failures decline to a minimum level, but then increase once again toward the end of the plant design life.

As a result, confidence is never a constant, but changes with time. For new facilities, a confidence index should be employed to promote early inspections to identify any active deterioration mechanism not identified through the RBI assessment. These inspections should include a general type of inspection (e.g., a thorough internal visual examination), which has the capability of detecting unexpected deterioration such as previously undetected manufacturing defects.

In the middle of the plant life when deterioration rates are confirmed by several inspections, inspection interval may be extended, provided in-service

inspections have confirmed the rate of deterioration is both reasonable and predictable. Toward the end of the plant life, when the equipment is approaching the end of its serviceable life, confidence in the integrity of the item is necessarily reduced and inspections performed more frequently.

#### 4.34.1.9.7 Realistic consequence modeling

Consequence modeling needs to be realistic for RBI to deliver a sensible inspection plan. Figure 8 shows a comparison of consequence of failure results for a

steam reformer plant using two different proprietary RBI software packages. As can be seen, the results are not at all comparable. Both RBI assessments are described as ‘semiquantitative,’ although the assessment methodologies are radically different.

The methodology employed in Figure 8(a) was a very simple consequence assessment using nine simple assessment criteria, which are answered with “yes,” “no,” or a simple number (size, temperature, pressure, etc.). Because of the simplicity of the methodology, the results are necessarily very conservative,

Figure 7 ‘Bath tub’ curve of hypothetical failure rate versus time.

Figure 8 Comparison of RBI consequence of failure assessments from two proprietary RBI software packages. Assessments cover the same piping from a refinery steam reformer plant. (a) Consequence of failure results from a proprietary RBI software package. (b) Consequence of failure results from an alternative proprietary RBI software package.

with 60% of items being given the highest possible rank for consequence of failure.

The second methodology is more complex, employing quantitative methods to calculate hazard areas for several failure scenarios. The technique is semiquantitative because it simplifies the dispersion modeling of any release into three specific phases (gas, dense gas, and liquid), and makes broad assumptions on repair times and mitigation systems. This technique is much less conservative, with only 2% of items being assigned the highest two consequence categories.

Clearly, the consequence of failure assessment methodology has a significant impact on the risk ranking results. A more conservative assessment will result in more items being considered critical, and this will drive more frequent inspections. However, overly conservative assessments do not give sufficient separation in risk ranking, and thus fail to focus inspection on those items that actually constitute the highest risk.

#### 4.34.1.9.8 Intelligent interpretation of inspection findings

A key factor in the success of any RBI program is feedback of inspection findings to the risk assessment. This sounds very simple, and yet in practice information gained from inspection activities is frequently not interpreted intelligently, leading to inappropriate use of inspection findings to revise the RBI assessment and consequently the revised inspection plan.

Intelligent use of inspection data is best illustrated through specific examples.

#### 4.34.1.10 Case Study 1: Corrosion Rate Trending

Corrosion rate trending is one of the most common plant inspection techniques, and is commonly performed using ultrasonic wall thickness (UTW) gauging. However, the UTW measurement technique has

a practical accuracy of  $\sim\pm 0.5$  mm, partly due to accuracy of the instrument itself, and partly due to repeatability of the probe placement in precisely the same location on a pipe for subsequent readings, and the fact that corrosion is frequently not uniform. Consequently, wall loss trends can be misleading.

Figure 9 shows different forms of corrosion, including general corrosion, bottom of the line corrosion, and top of the line corrosion, all of which are commonly found in process plant piping systems. Other common nonuniform forms of corrosion are pitting, preferential weld corrosion, and mesa attack. Measurements are typically taken at four cardinal points (normally 3, 6, 9, and 12 o'clock positions).

While a simple average of differences between two sets of wall thickness measurements in a system experiencing general corrosion may yield a sensible corrosion rate (assuming minimal errors from instrument calibration, probe placement, and thermal influences), in all instances where corrosion is nonuniform, the measured average corrosion rate will always be very optimistic. For instance, a straight average corrosion rate calculated for pipes in Figure 9 showing bottom of the line corrosion and top of the line corrosion would return a corrosion rate which is  $\sim 25\%$  of the actual worst case corrosion rate.

Use of proprietary software tools for trending UTW measurements is worldwide standard practice. These tools calculate corrosion rates for each thickness measurement location (TML) as well as an average corrosion rate for an entire corrosion loop. Two corrosion rates are normally reported; a short term corrosion rate (difference between the last and the previous reading), and a long term corrosion rate (difference between the first and last readings). These terms are illustrated in Figure 10, which shows actual wall thickness readings for a pipe in service.

Table 3 shows results from trending of the wall thickness data from the above and other TMLs from

Figure 9 Different forms of corrosion.

**Figure 10** Historical ultrasonic wall thickness readings for a pipe in service.

the same pipe. Trends using a proprietary software package, as well as standard statistical analysis are shown. The latter evaluates thickness measurements from the entire pipe, and seeks to eliminate inaccuracies arising from the measurement methodology and localized corrosion. Normally a reasonable evaluation of corrosion rate is obtained using a mean value plus one standard deviation.

Results displayed in [Table 3](#) demonstrate that it is possible to obtain very good agreement between the predicted corrosion rate and the experienced rate. Moreover, it demonstrates potential shortcomings with accepted methods of wall thickness trending.

#### 4.34.1.11 Case Study 2: Use of Robust RBI to Enhance Understanding of Inspection Data

Robust RBI likelihood modeling should provide insight into deterioration mechanisms that may be anticipated in service. This case study concerns linear indications discovered in a pipe to branch weld during a routine inspection, [Figure 11](#).

Areas of the process system in question were known to be susceptible to stress corrosion cracking due to CO and CO<sub>2</sub>. The initial assumption of the inspector, therefore, was that the pipe had suffered SCC, and a recommended repair was issued. The recommended repair was to coat the weld with a

coating system that has proven capability in mitigating this form of SCC.

Prior to approving the recommended repair, the RBI database was reviewed. This indicated that the susceptibility to SCC in this line was very low, as the pipe was a compressor discharge line which operates at warm and dry conditions.

The RBI analysis, however, did identify a potential susceptibility to mechanical fatigue, both due to vibrations from the compressor and the high velocity gas flow (calculations performed were simple screening calculations for flow induced vibration in accordance with the recommendations of the MTD guidelines).<sup>14</sup>

In the light of the RBI assessment, the recommended repair was altered, with the defect being removed by blend grinding.

#### 4.34.1.12 Case Study 3: Use of Robust RBI to Understand Plant Wide Integrity from Restricted Inspection Data

Inspections are generally task driven. A job card is raised to perform a specific inspection task on a specific item of equipment. In the event that the inspection identifies a degree of damage, the inspector may raise a recommendation for reparations to the item inspected. Once the reparations have been completed, the task is closed out. The weakness in this system is that information gained from any single inspection is rarely captured in order to infer the

**Table 3** UTW trends for using proprietary software and statistical analysis

	TML	Pipe
Trended long rate (UTW software product)	0.89	-0.63
Trended short rate (UTW software product)	-0.46	0.65
Statistical valuation (average + one standard deviation)	-	0.23
Prediction from proprietary RBI software package	-	0.23
Prediction from competitor RBI software package	-	0.62

**Figure 11** In-service cracking of a branch to header weld.

condition of areas of the process system that have not been inspected (e.g., upstream or downstream piping and equipment in similar service).

Use of robust RBI deterioration models facilitates a better understanding of inspection data. This case study concerns a refinery process unit which is similar in layout to a hydrotreater, [Figure 12](#).

The RBI assessment predicted a susceptibility to hydrochloric acid (HCl) corrosion in the reactor effluent heat exchangers. Prediction of HCl corrosion is difficult as corrosion rate is a function of chloride concentration (a few ppm), reactor temperature, and the stream water content, all of which are variable.

However, RBI assessments predicted low levels of corrosion in ES-101B/C and D, moderate corrosion in ES-101A, and severe corrosion in EA-101 and ES-102.

Inspections performed included visual examinations and UTW readings. The tube bundle in exchanger ES-102 suffered significant corrosion, and needed retubing within 2 years of commissioning. All other inspections reported superficial corrosion.

Authoritative review of inspection data included intelligent use of the wall thickness data, which confirmed no corrosion loss in the first heat exchanger (ES-101D), but noted that corrosion rate increased in each subsequent heat exchanger through to ES-102.

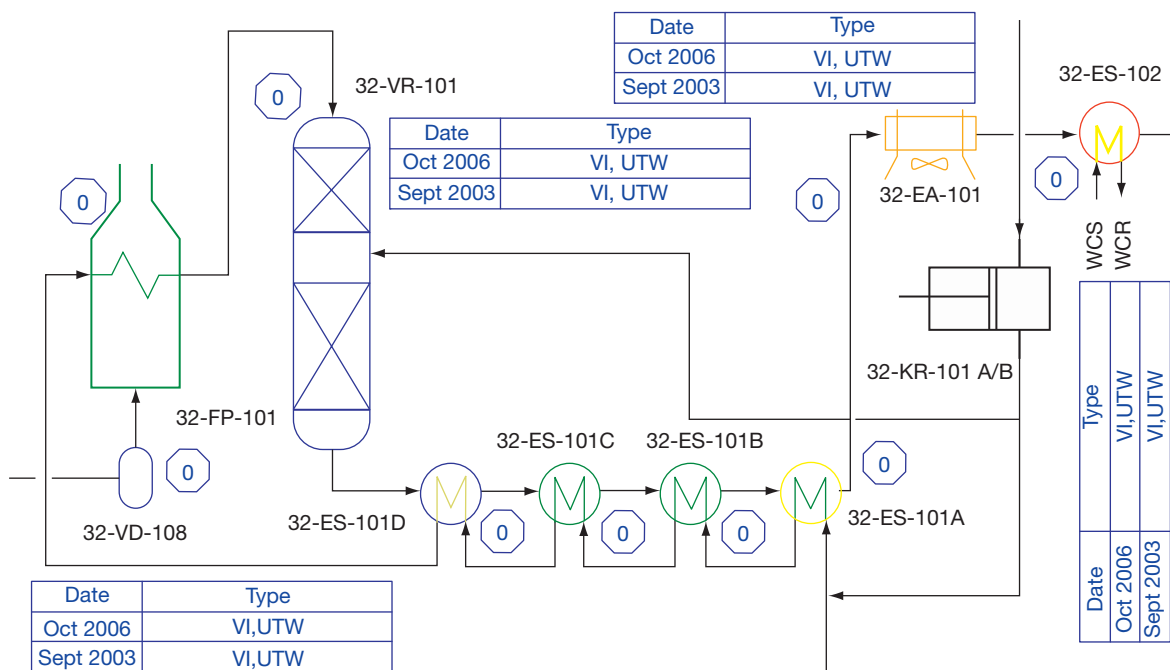

Interpretation of the inspection data in the light of RBI assessment confirmed the RBI predicted corrosion mechanism, and gave insight to the condition of the air cooled heat exchanger tubes, which had not been inspected directly. As the interpretation of corrosion threat was applied to the pressure system, rather than to just the items inspected, the air cooler was identified as a location for potentially significant deterioration, allowing the scheduling of Eddy current and IRIS inspections of the tubes to establish their condition.

#### 4.34.1.12.1 Efficient capture of process or hardware modifications

A common definition of madness is to keep doing the same thing and yet expect a different outcome. The opposite is also a true definition of madness; namely, to keep changing what you do and yet expect the same outcome.

In the modern, real world of process plant operations, process conditions are frequently changed. Oil and gas production facilities often experience changes in feedstock and pressure profile over the field life, for example, increasing water content, declining well pressure, increased H<sub>2</sub>S production, periodic reflux of well stimulation or work over fluids, etc. Petroleum refineries often source crude from various sources, introducing frequent feedstock changes; and plants are frequently run to optimize production to latest market needs.

These changes in feedstock or operating parameters may have a major impact on both likelihood and consequence of any failure, and need to be captured within the RBI system. Many RBI systems, however, are very time consuming to set up, and are inflexible to process changes. For instance, qualitative RBI assessments can rarely readily accommodate frequent changes as each change would require reconvening of the expert review team to assess significance of changes.

**Figure 12** Schematic of unit layout.

What is apparent is that the RBI process applied on a plant needs to be directly linked into the management-of-change (MoC) procedure as part of the overall AIM scheme. A properly applied MoC should encompass risks associated with all process and hardware changes. RBI can be used to assist this assessment and the MoC procedure should ensure that the RBI system is updated following each change.

#### 4.34.1.13 Major Challenges for RBI

There are a number of major challenges for RBI application development. These include:

- **Abnormal operations and upset conditions:** these are not currently modeled well in any RBI system because of the large uncertainties on the value and range of important parameters that might change during a process upset. The duration of any upset is also a very important parameter. At present, best practice is to review the RBI scheme following each process upset to either formally confirm that the specific upset had no effect on the existing risk level or specify actions to reassess the risk following the upset.
- **Possible degradation products:** no current RBI approach predicts with any great certainty the precise form and properties of degradation products. Material-process fluid interactions are capable of producing solids, liquids, and gases that may or may not initiate or contribute to further degradation. This is an issue of extending current RBI assessment practice to include secondary and tertiary effects of materials degradation within a process stream.
- **Batch operations:** current RBI approaches were designed for continuous operations. Risk can be accounted for by weighting anticipated corrosion rates with their respective service times. Complex batch operations, where several different chemicals are processed at different times, or where chemical cleaning cycles etc. may be included, are frequently covered inadequately.
- **Flexible operations (changing pressure, temperature, throughput, etc.):** as with batch operations, flexible operations often result in varying risk characteristics for each operating scenario. Consequently, careful thought needs to be afforded to the RBI assessment.
- **Changing feedstocks:** feedstock changes, which are often very subtle, are common and yet are frequently not adequately addressed in current RBI approaches. Consideration of the current and future process fluid chemistry and/or operating parameters at the start of an RBI planning project can assist in minimizing the risk of using inappropriate assumptions in the assessment. Sensitivity studies should be used to estimate the influence of changing parameters. Moreover, a robust RBI program should identify

key process parameters (e.g., pressure, temperature, chemical restrictions, operating mode, etc.) beyond which the RBI assessment is invalid.

- Areas where basic data may not be appropriate (e.g., deadlegs): conditions in deadlegs, piping, or equipment which are used infrequently and low flow areas which are not the same as those in the main process streams. Many RBI schemes fail to recognize these differences, and hence may significantly under estimate the risk in these locations. A sensible approach is to employ corrosion circuit assessments, which would require evaluation of the main flow, lines under intermittent flow, and deadlegs.

As RBI approaches develop, some challenges will be met and other new ones will appear. Many answers will come from improvements in plant operational software and developments in process modeling. As data becomes fully integrated, the opportunities to conduct rapid and accurate RBI assessment will become more common.

#### 4.34.1.14 Future Developments

Many consider that the goal of RBI must be to achieve the ability of the system to interrogate live process and operating data (e.g., digital control systems, corrosion monitoring, and direct inspection data) in order to give a real time integrity assessment, assessing the impact of actual operating conditions on plant integrity as they occur. Moreover, the risk and integrity status could be displayed on intelligent plant drawings (P and IDs, isometrics, equipment drawings, etc).

When RBI was first applied in the oil and gas industry this was something of a dream, but all the elements required to achieve it now exist and it is seemingly only a matter of time before it becomes reality.

### Glossary

**Defect** A metallurgical imperfection.

**Degradation** A detrimental change in the material by a metallurgical, electrochemical, or mechanical process, for example, precipitation, stress corrosion cracking, or fatigue.

**Failure** An event that results in a loss of structural integrity of a component containing a flaw.

**Failure assessment diagram** A graphical approach to quantify the structural integrity of a component containing a flaw in terms of failure by fracture or plastic collapse.

**Fitness for service assessment** Quantitative evaluation of the structural integrity of a

component containing a flaw carried out to a published procedure.

**Flaw** Any macroscopic metallurgical imperfection involving a discontinuity, such as a crack, solid inclusion, gas pore, etc.

**Limit load** The load applied to a structure at plastic collapse.

**Plastic collapse** The failure of a structure by the development of plastic strain across the net section.

## 4.35.1 Introduction

The safe design and reliable operation of engineering plant is critical to all industries. Design codes, such as those published by the American Society of Mechanical Engineers (ASME) for the process and power industries, provide clear rules for the design, fabrication, inspection, and proof testing of new plant prior to going into service.<sup>1</sup> However, as such codes are developed for engineering design (rather than operation), they do not fully consider that materials degrade in service by a range of mechanisms, including:

- metallurgical degradation (including graphitization, temper embrittlement, sigma phase embrittlement, strain ageing, and irradiation damage);
- mechanical degradation (including creep cavitation, erosion, mechanical and thermal fatigue, ductile tearing, and brittle fracture);
- chemical/electrochemical degradation (including oxidation, sulfidation, carburization and metal dusting, general and localized corrosion, corrosion-fatigue, stress-corrosion cracking, and erosion-corrosion).

Examples of material degradation by fatigue and stress-corrosion cracking are illustrated in [Figure 1](#).

- (a) Fatigue crack in 2024-T351 high strength aluminum alloy containing a tensile residual stress
- (b) Transgranular stress corrosion cracking in sensitized 304 stainless steel due to chloride contamination
- (c) Intergranular stress corrosion crack in sensitized 304 stainless steel exposed to high temperature oxygenated water

Since materials degrade and defects can initiate and propagate in engineering components during plant operation, there is an ongoing need to demonstrate the structural integrity of engineering components during service life, thus ensuring the continued safe and reliable operation of the plant. While nondestructive examination (NDE) methods provide information regarding the presence and development of crack-like flaws, fitness-for-service (FFS) assessment methodologies provide the means for judging the severity of such flaws and the consequence for component integrity. Such FFS methodologies have been developed to provide the engineer with clear guidance regarding: (i) the information required to undertake FFS assessment, (ii) the steps required to perform FFS assessment, and (iii) the information to be presented with respect to the results of FFS

assessment. The results from such assessments provide the plant operator with valuable information that may be used to inform decisions regarding component operation, component repair, and (or) component replacement. These results also form part of the development of safety cases to support the continued operation of plant components.

There are a number of FFS assessment methodologies used within the process and power industries world-wide, including:

- BS 7910:2005, 'Guide to methods for assessing the acceptability of flaws in metallic structures', British Standards Institution, 2005;
- R6 Revision 4, 'Assessment of the integrity of structures containing defects', British Energy Generation Ltd, 2006;
- API 579, 'Fitness for Service', American Petroleum Institute Recommended Practice, 2000;

- FITNET MK7, 'Fitness-for-service procedure' European Fitness for Service Thematic Network (FITNET TN), 2006.

Common to each of these procedures is the failure assessment diagram (FAD) approach for assessing the significance of crack-like flaws which may be present at the start of a component's life (e.g., lack of fusion weld defect) or which may form during service (e.g., by one or more of the degradation mechanisms outlined above). A typical FAD is illustrated in [Figure 2](#).

This chapter describes the FAD approach to structural integrity assessment. [Section 4.35.2](#) provides a brief overview of the different components of the FAD. [Section 4.35.3](#) describes the  $L_r$  parameter while [Section 4.35.4](#) provides a description of the  $K_r$  parameter. Finally, [Section 4.35.5](#) presents a working example of the use of the FAD approach to assess a component containing a flaw. This chapter

**Figure 1** Examples of crack-like flaws in engineering materials.

**Figure 2** Failure assessment diagram.

should be read alongside the chapter on the mechanical and fracture properties of materials in this book, which provides important background material.

#### 4.35.2 Overview of the Failure Assessment Diagram

The FAD is a graphical representation of the acceptability or unacceptability of a crack-like flaw in a given component under particular operating conditions. As shown in [Figure 2](#), the FAD includes a ‘failure assessment curve’ and ‘failure assessment point’.

The FAD provides the means for judging the proximity of a component to failure by either plastic collapse (‘bending’) or fracture (‘breaking’). The FAD is plotted with an abscissa  $L_r$ , which defines the proximity of the component to plastic collapse, and an ordinate  $K_r$ , which defines the proximity of the component to unstable fracture. Plastic collapse usually controls component failure when the flaw is large relative to the thickness of the component and the material has high fracture toughness and low yield stress. Unstable fracture usually controls component failure when the defect is small relative to the thickness of the component and when the material has low fracture toughness (e.g., brittle materials) with high yield strength.

The failure assessment curve defines the boundary between acceptable (or safe) and unacceptable (or unsafe) regions with respect to component failure by unstable fracture or plastic collapse. The curve may be defined in a general manner (as shown in [Figure 2](#)) by the following equation:

$$K_r = (1 - 0.14L_r^3)(0.3 + 0.7\exp[-0.65L_r^6]) \text{ for } L_r \leq L_{r(\max)} \quad [1]$$

The maximum extent or ‘cut-off’ of the failure assessment curve on the  $L_r$  axis is determined by the ratio of the material flow stress  $\sigma_f$  (the average of the yield and ultimate tensile stress) and material yield stress  $\sigma_y$  at the temperature of interest, that is,

$$L_{r(\max)} = \frac{\sigma_f}{\sigma_y} \quad [2]$$

The yield stress is conventionally defined by the 0.2% proof stress  $\sigma_{0.2}$  of the material. Typical cut-off values are shown in [Figure 2](#), and are due to the significant differences of work hardening behavior. They include:

- $L_{r(\max)} = 1.00$  for materials with a yield plateau
- $L_{r(\max)} = 1.25$  for carbon–manganese steels
- $L_{r(\max)} = 1.80$  for austenitic stainless steel

The failure assessment point defines the position of a specific flaw in a specific component under specific operating conditions with respect to the failure assessment curve. If the point lies below the failure assessment curve, the flaw is deemed to be acceptable (the component is safe) and the flaw may be left in service with no impact on the operational safety or the structural integrity of the component. However, if the failure assessment point lies outside the failure assessment curve, the flaw is deemed to be unacceptable (the component *may be* unsafe) and corrective action may be necessary, for example, the repair or replacement of the component. The assessment used commonly has significant conservatism due to simplifications in the analysis. In some cases, a more sophisticated reassessment of the flaw, with reduced conservatism, may be sufficient to demonstrate that the component is, in fact, safe.

To define the location of the failure assessment point, the parameters  $L_r$  and  $K_r$  need to be calculated for the component containing a given flaw under the operating conditions of interest.

The parameter  $L_r$  is defined by the ratio of the reference stress  $\sigma_{\text{ref}}$  to the materials yield stress  $\sigma_y$  at the temperature of interest, that is,

$$L_r = \frac{\sigma_{\text{ref}}}{\sigma_y} \quad [3]$$

Where  $\sigma_{\text{ref}}$  is defined from the knowledge of the dimensions of the flaw and the stress acting on the flaw under the operating conditions of interest. The yield stress,  $\sigma_y$ , is usually defined from a standard tensile test using the 0.2% proof stress  $\sigma_{0.2}$ . An equivalent definition of  $L_r$  is as follows:

$$L_r = \frac{P}{P_L} \quad [4]$$

where  $P$  is the load applied to the structure and  $P_L$  is the limit load. The parameter  $L_r$  is discussed in greater detail in [Section 4.35.3](#).

The parameter  $K_r$  is defined under *primary* loading (see [Section 4.35.3](#)) by the ratio of the linear elastic stress intensity factor  $K_I$  to the material fracture toughness  $K_{\text{mat}}$  at the temperature of interest, that is,

$$K_r = \frac{K_I}{K_{\text{mat}}} \quad [5]$$

where  $K_I$  is defined from the knowledge of the component geometry, the dimensions of the flaw, and the

stress acting on the component under the operating conditions of interest. The material fracture toughness is defined by fracture toughness testing of the component material at the temperature of interest. The parameter  $K_r$  is described in further detail in [Section 4.35.4](#).

### 4.35.3 The $L_r$ Parameter

The calculation of the  $L_r$  parameter in FFS assessment not only requires the definition of the material yield stress  $\sigma_y$  (conventionally defined by  $\sigma_{0.2}$ )<sup>1</sup> but also an understanding of the stress condition of the component being assessed. In FFS assessment, this understanding must take full account of all the stresses acting on the component. There are broadly three types of stress that can act on an engineering component:

1. applied stresses such as those due to internal pressure,
2. thermal stresses such as those due to thermal transients, and
3. internal (residual) stresses such as those due to welding.

For the definition of the  $L_r$  parameter, only the applied stresses are considered. Such stresses are necessary to satisfy equilibrium conditions with externally imposed loading and are defined as 'primary' stresses  $\sigma^p$ . These contribute to the plastic collapse of a structure (e.g., as pressure is increased within a pressure vessel or pipe). Thermal and internal stresses are necessary to satisfy continuity conditions within the structure (e.g., weld residual stress) or with an external constraint (e.g., pipe fit-up stress). Such stresses are defined as 'secondary' stresses  $\sigma^s$ . Secondary stresses do not significantly contribute to plastic collapse as these stresses will, in most cases, be self-equilibrating, that is, the net force and bending moment will be zero, and their effect will be effectively 'washed out' as plasticity extends across the ligament. The following definition of stresses is given within the R6 defect assessment procedure<sup>2</sup>:

- Primary stresses  $\sigma^p$  arise from loads that contribute to plastic collapse.
- Secondary stresses  $\sigma^s$  arise from loads that do not contribute to plastic collapse.

A more complete discussion of primary and secondary stresses is given in Lu *et al.*<sup>3</sup>

The application of a primary stress lower than the yield stress to an uncracked component will result in

elastic deformation of the component, as defined by Young's modulus and Poisson's ratio. However, for components containing crack-like flaws, the stress concentrating effect of the flaw can lead to local yielding of the material at the tip of the flaw. A zone of plastically deformed material surrounded by elastic material will develop at the tip of the flaw. Increasing the applied stress will expand this plastic zone until plasticity first extends across the uncracked ligament to the wall of the component. This condition is defined as the 'local collapse condition.' Further increases in applied stress lead to the uncracked ligament becoming fully plastic. This condition is defined as the 'net section collapse' condition. Finally, when the additional increases in applied stress cause the component to become fully plastic, 'gross collapse' of the component has occurred. It is important to note that under some circumstances the flaw will extend under an increasing primary load, for example, by ductile tearing. Crack growth will reduce the dimension of the uncracked ligament and increase the likelihood of plastic collapse.

These three limiting conditions are illustrated schematically in [Figure 3](#) for an axially cracked pipe under an internal pressure  $p$ :

- *Local collapse* occurs when the plasticity first extends across the uncracked ligament ahead of the flaw.
- *Net section collapse* occurs when the uncracked ligament becomes fully plastic.

**Figure 3** Schematic illustration of plastic collapse solutions for a pressurized cylinder containing an axial flaw. The dark shaded regions indicate the region of plasticity. (a) Local collapse, (b) net section collapse, and (c) gross collapse.

- *Gross collapse* occurs when plasticity extends across the full component thickness.

The ‘failure’ of a component by plastic collapse may be defined at each of these conditions.

The reference stress  $\sigma_{\text{ref}}$  defines the effective primary ligament stress (for local collapse) or the effective net section stress (for net section collapse) within the component containing a defect under an applied primary stress. Compendia of standard equations defining  $\sigma_{\text{ref}}$  for a wide range of cracked geometries are available within FFS procedures such as in R6 Revision 4<sup>2</sup> and API 579.<sup>4</sup>

Equation [4] shows that  $L_r$  can be defined with reference to the applied load on a structure normalized by the limit load for the structure.

For example, the following equation defines the reference stress with respect to the net section collapse of the cracked cylinder shown in Figure 3<sup>4</sup>

$$\sigma_{\text{ref}} = \frac{\sigma_b + [\sigma_b^2 + 9\{M_s\sigma_m\}^2]^{0.5}}{3} \quad [6]$$

where  $\sigma_b$  is the through wall primary bending stress,  $\sigma_m$  is the primary membrane stress intensity, and  $M_s$  is a surface correction factor for a surface crack. The membrane stress is defined as the average stress across the thickness of a section. The bending stress is the bending component of the stress acting across the same section. The surface correction factor is required to take into account the local effect of the crack on the membrane and bending and stresses on the cracked plane. The primary bending and membrane stresses are dependent on the internal pressure and thickness of the diameter and wall of the cylinder. The parameter  $M_s$  is dependent on the ratio of crack depth to the cylinder wall thickness.

#### 4.35.3.1 Example Calculation of $L_r$

This example calculation is based on the axially cracked cylinder geometry illustrated in Figure 3 with the following parameters:

Material	AISI Type 304L stainless steel
Temperature	20°C
Internal radius ( $R_i$ )	120 mm
Outer radius ( $R_o$ )	132 mm
Wall thickness ( $t$ )	12 mm
Crack depth ( $a$ )	4.8 mm
Internal pressure ( $p$ )	10 MPa

Step 1. Define the yield stress  $\sigma_y$  of the material at the temperature of interest.

The yield stress of AISI 304L stainless steel at 20 °C is given as 210 MPa using the Matweb database.<sup>5</sup>

Step 2. Define the reference stress  $\sigma_{\text{ref}}$  for the cracked component of interest.

Using eqn [6] along with the stress solutions given in API 579,<sup>4</sup> the parameters  $P_m$ ,  $P_b$ , and  $M_s$  are given as follows:

$$P_m = \frac{pR_i}{t} \quad [7]$$

$$P_b = \frac{pR_o^2}{R_o^2 - R_i^2} \left[ \frac{t}{R_i} - \frac{3}{2} \left( \frac{t}{R_i} \right)^2 + \frac{9}{5} \left( \frac{t}{R_i} \right)^3 \right] \quad [8]$$

$$M_s = \frac{1}{1 - a/t} \quad [9]$$

Inserting the parameters of interest into these equations gives  $P_m = 100$  MPa,  $P_b = 5$  MPa, and  $M_s = 1.67$ . Inserting these parameters into eqn [6] gives the reference stress for this component and internal pressure of  $\sigma_{\text{ref}} = 168$  MPa.

Step 3. Calculate  $L_r$ .

$L_r$  is defined as  $\sigma_{\text{ref}}/\sigma_y$ . Therefore, for this component geometry, defect size and internal pressure,  $L_r = 168/210 = 0.80$ .

#### 4.35.4 The $K_r$ Parameter

The  $K_r$  parameter quantifies the proximity of the component to failure by fracture in the elastic or small-scale yielding regime of the FAD when  $L_r$  is small. Under these circumstances, if the failure assessment point lies outside the failure assessment curve (the unacceptable region); the component would be assessed to fail by fracture with very limited plastic deformation, that is, the plastic zone is typically less than one-twentieth the size of the uncracked ligament. This condition is illustrated schematically in Figure 4(a), where the crack-tip plastic zone size is small compared with the dimensions of the uncracked ligament just prior to fracture. Failure at intermediate levels of  $L_r$  is shown in Figure 4(b). Within this region, failure occurs with more extensive plasticity emanating from the tip of the crack, such that just prior to the fracture, the plastic zone size is a significant proportion of the uncracked ligament. In contrast to this, and as discussed in the previous Section, failure by plastic-collapse occurs due to the development of plasticity across the full uncracked ligament, Figure 4(c).

**Figure 4** Schematic illustration of failure by (a) fracture in the elastic or small-scale yielding regime, (b) failure in the elastic-plastic regime, and (c) failure by net section plastic collapse. The dark shaded regions indicate the region of plasticity.

Fracture under linear-elastic or small-scale yielding conditions usually controls component failure when the flaw is small relative to the thickness of the component and when the material has low fracture toughness and high yield stress.

Only under primary loading, the parameter  $K_r$  is defined by the ratio of the linear elastic stress intensity factor  $K_I$  to the fracture toughness  $K_{mat}$  of the material at the temperature of interest. The fracture toughness is defined with respect to the failure mode of interest, that is, cleavage fracture toughness for ferritic materials operating at temperatures within the cleavage fracture regime, or ductile fracture toughness for austenitic stainless steels. For FFS assessment of ductile materials in normal operating conditions, the ductile fracture toughness normally relates to the initiation of ductile tearing, or the fracture toughness at 0.2 mm of stable ductile tearing as measured in a standard fracture mechanics test at the temperature of interest. For ductile materials under particularly infrequent loading scenarios (e.g., postulated accident conditions) some benefit may be taken from the enhanced level of fracture toughness associated with up to 2 mm ductile tearing. However, such FFS assessments would normally be judged on a case-by-case basis.

The fracture failure condition is defined when  $K_I = K_{mat}$ , or equivalently when  $K_r = 1$ . The reader

is referred to **Chapter 1.04, Mechanical Properties and Fracture of Materials** for a full description of the stress intensity factor and the fracture toughness.

#### 4.35.4.1 Example Calculation of $K_r$

This sample calculation is based on the geometry illustrated in **Figure 4** with the following parameters:

Material	AISI Type 304L stainless steel
Temperature	25 °C
Internal radius ( $R_i$ )	120 mm
Outer radius ( $R_o$ )	132 mm
Wall thickness ( $t$ )	12 mm
Crack depth ( $a$ )	8.6 mm
Internal pressure ( $p$ )	10 MPa

Step 1. Define  $K_I$  for the cracked component of interest.

The following equations are used along with the factor parameters  $G_0$  to  $G_4$  given in API 579<sup>4</sup> to define the stress  $\sigma$  and the geometry term  $Y$  for the geometry of interest, that is,  $R_i/t = 10$  and  $a/t = 0.4$ .

$$K_I = \sigma Y \sqrt{\pi a} \quad [10]$$

$$\sigma = \frac{p R_o^2}{(R_o^2 - R_i^2)} \quad [11]$$

$$Y = 2G_0 - 2G_1 \left( \frac{a}{R_i} \right)_1 + 3G_2 \left( \frac{a}{R_i} \right)^2 - 4G_3 \left( \frac{a}{R_i} \right)^3 + 5G_5 \left( \frac{a}{R_i} \right)^4 \quad [12]$$

Inserting the geometry parameters of interest and magnitude of the internal pressure into eqns [11] and [12] gives  $\sigma = 48$  MPa and  $Y = 7.6$ . Using these parameters along with eqn [10] gives the Mode I stress intensity factor for this component and internal pressure of  $K_I = 60$  MPa  $\sqrt{m}$ .

Step 2. Define the fracture toughness  $K_{mat}$  of the material at the temperature of interest.

The fracture toughness AISI 304L stainless steel at 25 °C is given as 230 MPa  $\sqrt{m}$  in Snead *et al.*<sup>6</sup>. Note that fracture toughness properties can vary from cast to cast, with heat treatment, material processing, test temperature, and specimen size. However, this value is considered suitable for illustrative purposes.

Step 3. Calculate  $K_r$

Only Under primary loading,  $K_r$  is defined as  $K_I/K_{mat}$ . Therefore, for this component geometry, defect size and internal pressure,  $K_r = 60/230 = 0.26$ .

#### 4.35.5 The Assessment of Corrosion Defects

This section provides an overview of the guidance provided within the European FITNET procedure for the assessment of corrosion defects.<sup>7</sup> FITNET was a 4-year European thematic network with the objective of developing and extending the use of FFS procedures throughout Europe. The principles of the FITNET procedure are consistent with other assessment methods including BS 7910:2005,<sup>8</sup> R6,<sup>2</sup> and API 579.<sup>4</sup>

The FITNET assessment procedure follows a five-step process:

- Step 1: Characterize the nature of the crack
- Step 2: Establish the cause of cracking
- Step 3: Define the material characteristics
- Step 4: Establish data for stress corrosion cracking assessment
- Step 5: Undertake structural integrity assessment

Each of these steps is described in the following sections.

##### 4.35.5.1 Step 1: Characterize the Nature of the Crack

The NDE of plant components by a range of methods is an important aspect to demonstrating FFS. Once a

defect is located, as much information as possible should be gathered regarding the nature of the crack (or cracks). This should include (though not necessarily be limited to) the following:

- Crack size and shape, including length and depth
- Crack location
  - Relative to stress concentration, weld, crevice
  - Crack path and crack orientation
- If more than one crack is present
  - Crack number density
  - Spacing between cracks
- State of surface
  - General or localized corrosion damage
  - State of coating (if present)

The information gathered will not only provide valuable inputs for FFS assessment, but will also yield information which may guide the focus of future NDE. **Figure 5(a)** illustrates the surface of a 304 stainless steel that has been contaminated by magnesium chloride solution and exposed in a humid atmosphere (60% relative humidity) at 60 °C under a tensile stress. Corrosion pits and a linking stress corrosion crack are visible. A metallographic section taken perpendicular to the crack plane reveals the crack to be substantially transgranular and extremely branched in nature, **Figure 5(b)**.

**Figure 5** (a) Surface corrosion damage in 304 stainless steel contaminated with magnesium chloride and exposed to humid air (60% relative humidity) at 60 °C under stress, (b) metallographic section a2 revealing transgranular and branched stress corrosion crack initiated at corrosion pit. Reproduced from, Eble, O.R. M.Sc. Dissertation, *Corrosion and Protection Centre*; The University of Manchester, 2006.

### 4.35.5.2 Step 2: Establish the Cause of Cracking

Since SCC results from a critical combination of environment, stress and a susceptible material, it is important that these three factors should all be understood. Step 2 focuses on clarifying the first two of these, that is, the service environment and the local stress condition. The nature of the material is considered under Step 3.

#### 4.35.5.2.1 Service environment

An understanding of the service environment is important in helping to understand the nature of cracking. This includes factors such as chemistry (including pH, electrochemical potential, and composition including impurities), humidity and temperature.

While the bulk environment may be well understood and controlled, it is important to note that local environmental conditions can develop within, for example, crevices, under deposits, within dead spaces, etc. Such local environmental conditions are often the cause of corrosion-related problems. Factors that should be considered include the level of impurity ions by ion migration, for example, chloride, and concentration processes, for example, due to evaporation.

Excursions from the normal service environment and (or) temperature during the operation of the plant can result in the development of SCC, even though the normal environment is one which might not normally be a concern. Consequently an understanding of the service history can be critical in providing an understanding of the cause of cracking. Under such circumstances, corrosion monitoring systems can be invaluable in identifying occasions when susceptibility to SCC cracking might have been increased.

#### 4.35.5.2.2 Stress

A knowledge of the service loads is also important both in developing an understanding of the cause of cracking and in providing input data to the FFS assessment. These may include:

- applied stresses such as internal pressure
- thermal stresses due to temperature gradients or thermal shocks
- internal (residual) stresses due to manufacturing processes such as welding.

The presence of significant cyclic stresses may lead to the development of fatigue or corrosion–fatigue cracks. Transient stresses, for example, pressure

during the startup or shutdown of equipment, are often important in inducing the propagation of SCC cracks.

In quantifying the stresses, it is important that distinction is made between primary and secondary stresses (as discussed in [Section 4.35.3](#)), that is, primary stresses arise from loads that contribute to plastic collapse and secondary stresses arise from loads that do not contribute to plastic collapse.

#### 4.35.5.2.3 Crack morphology

Within the FITNET procedure, environmentally-assisted cracking under both static (SCC) and cyclic (corrosion–fatigue) loading conditions are considered. The morphology of cracking is often different in each case. For example, corrosion–fatigue cracks are often limited to a single crack path, while SCC cracks can exhibit significant branching ([Figure 5\(b\)](#)). Recognition of the crack morphology can thus provide valuable information regarding the cause of cracking.

### 4.35.5.3 Step 3: Define the Material Characteristics

It is important to ensure that the material that makes up the component is that which was specified during the design and manufacture of the component. In many cases, problems associated with the development of cracks have been attributed to the incorrect selection of material during manufacture, repair, or replacement of the component.

There are a number of particular material factors which will influence the performance of the component. These can arise from the manufacturing process and also from microstructural changes that occur in service. These factors include the following.

#### 4.35.5.3.1 Surface condition

The condition of a surface can significantly influence the subsequent performance of a component. The surface of a material has a number of component parts, which can be divided into four main headings:

- Topography
- Chemistry
- Metallurgy
- Mechanical properties

These may be considered external and internal features. [Figure 6](#), adapted from Griffiths,<sup>9</sup> illustrates the various aspects that contribute to the external and internal features of a surface.

**Figure 6** Summary of key external and internal features which characterize a surface. Adapted from Griffiths, B. *Manufacturing Surface Technology: Surface Integrity and Functional Performance*; Penton Press: London, 2001.

With respect to the initiation of SCC cracks, the key features include surface roughness, which in laboratory specimens is used to study corrosion susceptibility and may typically be of the order of  $1\ \mu\text{m}$ . In plant components, rough machining by grinding, for example, can result in extremely rough surfaces, which also contain a significant degree of plastic deformation (cold work), microstructural damage, and high internal residual stresses. These can all combine to increase the susceptibility to SCC. **Figure 7** illustrates the influence of typical machining (lathe turning) parameters on surface roughness and residual stress in a recent study performed on austenitic stainless steel.<sup>10</sup>

It should be noted that while surface residual stress levels may be tensile, this will be balanced by compressive stresses within the bulk material. Initiating SCC cracks can, under some circumstances, arrest once the tip of the crack reaches the compressive residual stress region.

#### 4.35.5.3.2 Welding

Welds are often a likely region for the development of SCC cracks for two primary reasons. First, weld microstructures are complex and often contain regions of susceptibility to SCC. For example, grain boundary sensitization (chromium depletion) can occur as a result of welding austenitic stainless steels as the parent metal in the heat affected zone (HAZ) cools through the critical temperature range for carbide precipitation  $\sim 850\text{--}450\ ^\circ\text{C}$ . Other microstructural factors can include elongated and clustered inclusions and crystallographic texture. Secondly, residual stress levels can be high, particularly in non stress-relieved welds. In such circumstances, the

**Figure 7** Influence of machining parameters on surface roughness and surface residual stress of austenitic stainless steel. Reproduced from Kuroda, M.; Marrow, T. J. *J. Mater. Process. Technol.* **2006**, 203(1–3), 396–403.

tensile stress level in the vicinity of a weld can be of yield magnitude. Stress concentrating features including undercuts can also provide local geometric features which enhance SCC susceptibility.

#### 4.35.5.3.3 Initial microstructure

In addition to the factors described above, manufacturing history is also an important factor to consider. For example, rolled plates contain heavily elongated grains aligned in the rolling direction. The morphology

of the grain structure, including local texturing, combined with its influence of mechanical properties, can influence SCC susceptibility.

#### 4.35.5.3.4 Materials ageing

Material microstructure (and hence properties) can often evolve during service as a result of thermal and (or) environmental factors. For example, extended operation of stainless steels at elevated temperatures can lead to the precipitation of chromium carbides and the consequent local depletion of chromium. Cast austenitic stainless steels, which generally contain some residual ferrite, can undergo a spinodal decomposition of the ferrite with an impact on hardness and toughness. Materials operating in a neutron flux such as core internal components of nuclear reactors, will undergo irradiation-induced microstructural changes which can include grain boundary sensitization (without chromium carbide precipitation) and matrix hardening (due to the formation of lattice defects such as vacancies and interstitials, dislocation loops and copper-rich clusters).

#### 4.35.5.4 Step 4: Establish Data for Stress Corrosion Cracking Assessment

The parameter used to assess SCC crack growth rates is  $K_{ISCC}$  which defines the threshold stress intensity factor for sustained crack growth, **Figure 8(a)**. There is a region of applied  $K_I$  below which SCC crack growth is not well characterized. Within this region

the driving force for SCC crack growth may either be too low (and SCC does not occur) or may be stress-controlled. As the applied  $K_I$  increases above  $K_{ISCC}$  the crack growth rate rises rapidly to a plateau. It is important to note that the magnitude of both  $K_{ISCC}$  and the crack growth rate plateau are material and environment-dependent. For example, **Figure 8(b)** reproduced from Cottis<sup>11</sup> shows the influence of copper content on SCC crack growth properties for Al–Cu–Mg alloys. This dependence of SCC crack growth rate with  $K_I$  is in contrast to other failure modes such as fatigue or corrosion–fatigue. Under cyclic loading, the crack growth rate per cycle is controlled by the difference between the maximum and minimum stress intensity factors,  $\Delta K_I$ . A higher  $\Delta K_I$  leads to a more rapid crack growth rate per cycle.

There are a number of issues which should be considered in the measurement and application of  $K_{ISCC}$  data. These include:

- $K_{ISCC}$  will depend on the environment, material condition, and loading configuration used. The conditions used to generate the data should reflect as closely as possible the service conditions of interest.
- The timescales used to generate  $K_{ISCC}$  are often shorter than typical plant operation timescales. Rate effects should be considered.
- While  $K_{ISCC}$  testing is conventionally carried out under static loading, service loading (as we have seen) often includes periodic unloads and reloads (e.g., due to startup and shutdown). Under such circumstances  $K_{ISCC}$  may be affected.

**Figure 8** (a) Schematic illustration of SCC crack growth rate as a function of applied  $K_I$ , and (b) SCC data for Al–Cu–Mg alloys of varying copper content. Reproduced from Cottis, R. A. *Guides to good practice in corrosion control: stress corrosion cracking*, NPL Report, 2000.

ISO 7539-6: 2003<sup>12</sup> provides guidance regarding the generation of  $K_{ISCC}$  data using precracked laboratory specimens loaded under fixed load or fixed displacement conditions.

#### 4.35.5.5 Step 5: Undertake Structural Integrity Assessment

The structural integrity assessment is undertaken with respect to the FAD approach described in detail within the first part of this chapter. **Figure 9** summarizes the key elements of the FAD, as described previously.

There are typically five stages in this assessment:

Stage A: Perform a fracture assessment for the initial crack size. If the failure assessment point lies within the acceptable region, and the size of the crack is significantly smaller than the thickness of the component, preventative measures should be considered to limit further growth of the crack. These may include reducing applied stresses and modifying the environmental chemistry or temperature.

Stage B: If preventative measures cannot be applied and subcritical crack growth can be tolerated, steps 1–4 should be followed to fully characterize: (a) the nature of cracking, (b) the environment, stress level, and material of concern, and (c) material

properties to quantify SCC crack growth rate for the material/environment combination of interest.

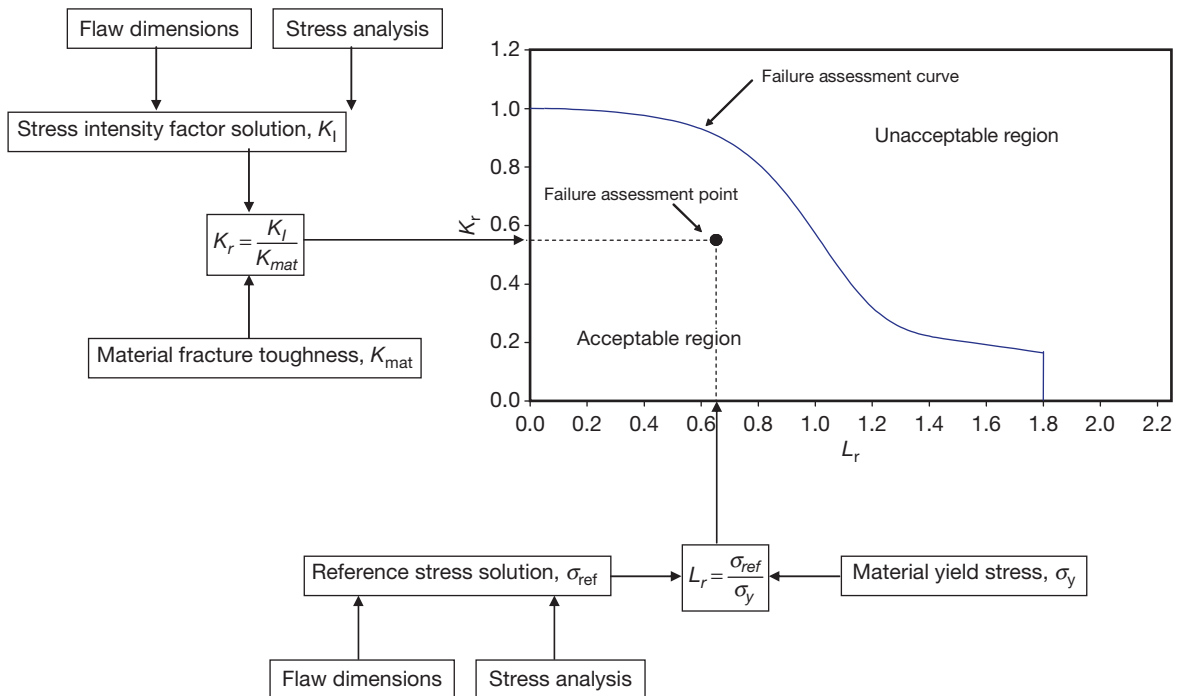

Stage C: Calculate the stress at the crack location, including applied, thermal, and internal stresses as appropriate.

Stage D: Determine the rate of increase of the size of the crack according to the crack growth law appropriate to the material/environment combination of interest.

Stage E: Determine the time for the current size of the crack to reach the critical crack size, including an appropriate in-service safety margin. This is undertaken by performing a series of FFS assessments and plotting a series of failure assessment points, each applicable to a given crack size, on the FAD. The critical crack size is defined when the failure assessment point lies on the failure assessment curve. Inspection intervals can be defined on the basis of such calculations, providing evidence that the growth rate is above or below that used in the assessment.

#### 4.35.6 Worked Example FFS Assessment

A flat plate component of width  $2W = 100$  mm and thickness  $t = 25$  mm is under a normal operating

**Figure 9** Summary of the key components of the failure assessment diagram.

membrane stress  $\sigma_m = 100$  MPa. As shown in **Figure 10**, a semielliptical flaw of depth  $a = 5$  mm and surface-breaking length  $2c = 50$  mm has been discovered in the component by nondestructive examination. The material fracture toughness is equal to  $40 \text{ MPa}\sqrt{\text{m}}$ , the yield stress is equal to  $450 \text{ MPa}$ . Stress corrosion cracking data for the material and environment of interest suggest that  $K_{\text{ISCC}}$  is equal to  $10 \text{ MPa}\sqrt{\text{m}}$  for this material and environment. Above this stress intensity factor, both  $a$  and  $c$  will increase at a rate of  $1 \text{ mm}$  per annum.

- Plot the failure assessment point on the FAD to demonstrate whether the component is safe to continue operation.
- Use the FAD approach to estimate: (i) the maximum membrane stress that the component can withstand before failure and (ii) the maximum safe life of the component under normal operating stress.

#### 4.35.6.1 Worked Example Part A

##### 4.35.6.1.1 Calculation of $L_r$

The reference stress for the geometry shown in **Figure 10** is defined by Solution D3.4 in API 579<sup>4</sup> as:

$$\sigma_{\text{ref}} = \frac{gP_b + [(gP_b)^2 + 9P_m^2(1 - \alpha^2)]^{0.5}}{3(1 - \alpha)^2} \quad [13]$$

**Figure 10** Schematic illustration of a flat plate component containing a semielliptical flaw of depth  $a$  and surface breaking length  $2c$  under an applied tensile membrane stress  $\sigma_m$ .

where

$$g = 1 - 20\left(\frac{a}{2c}\right)^{0.75} \alpha^3 \quad [14]$$

$$\alpha = \frac{a/t}{1 + t/c} \quad \text{for } W \geq (c + t) \quad [15]$$

and  $P_b$  is the through-wall primary bending stress component equal to zero in this example and  $P_m$  is the primary membrane stress component equal to  $\sigma_m$  in this example. This solution assumes that any induced bending of the plate due to the presence of the defect is restrained.

Using the dimensions of the component and defect, the parameter  $\alpha$  is equal to

$$\alpha = \frac{5/25}{1 + 25/25} = 0.1 \quad [16]$$

The parameter  $g$  is equal to

$$g = 1 - 20\left(\frac{5}{50}\right)^{0.75} 0.1^3 = 1 - 3.556 \times 0.001 = 0.996 \quad [17]$$

The reference stress is therefore equal to

$$\begin{aligned} \sigma_{\text{ref}} &= \frac{0.996 \times 0 + [(0.996 \times 0)^2 + 9 \times 100^2 (1 - 0.1^2)]^{0.5}}{3 \times (1 - 0.1)^2} \\ &= \frac{[89100]^{0.5}}{2.43} = 123 \text{ MPa} \end{aligned} \quad [18]$$

Since  $L_r = \sigma_{\text{ref}}/\sigma_y$ , for the defect found  $L_r = 123/450 = 0.27$ .

##### 4.35.6.1.2 Calculation of $K_I$

The stress intensity factor for the geometry shown in **Figure 10** is defined by Solution C3.4 in API 579<sup>4</sup> as

$$K_I = (M_m \sigma_m + M_b \sigma_b) \sqrt{\frac{\pi a}{Q}} \quad [19]$$

Where  $M_m$  and  $M_b$  are the membrane and bending correction factors, respectively,  $\sigma_b$  is the applied bending stress (equal to zero in this example) and  $Q$  is a geometry factor given by

$$\begin{aligned} Q &= 1.0 + 1.464\left(\frac{a}{c}\right)^{1.65} \quad \text{for } a/c \leq 1.0 \\ &= 1.0 + 1.464\left(\frac{5}{25}\right)^{1.65} \\ &= 1.0 + 0.103 = 1.103 \end{aligned} \quad [20]$$

The membrane correction factor  $M_m$  is dependent upon the plate and defect geometry as well as the location on the defect front of interest. Since the stress intensity factor is maximum at the deepest

**Figure 11** Failure assessment diagram for semielliptical flaw ( $a = 5$  mm,  $2c = 50$  mm) in a flat plate under membrane stress of 100 MPa.

point of the defect, this location is used to define  $K_I$ . Using the equations provided in API 579,<sup>4</sup> the membrane correction factor  $M_m = 1.217$ .

The stress intensity factor at the deepest point on the defect is thus given by

$$K_I = (1.217 \times 100) \sqrt{\frac{\pi \times 0.005}{1.103}} = 121.7 \times 0.119 = 14.5 \text{ MPa}\sqrt{\text{m}} \quad [21]$$

Since  $K_r = K_I/K_{mat}$ , for the defect found  $K_r = 14.5/40 = 0.36$

#### 4.35.6.1.3 Plotting failure assessment point on FAD

The failure assessment point for the component shown in Figure 10 is simply plotted on the general FAD using the values calculated for  $K_r$  and  $L_r$  above, along the general failure assessment curve defined by eqn [1]. The result, illustrated in Figure 11, shows that the point lies below the failure assessment curve and therefore within the 'acceptable' region of the diagram. The component is thus safe to continue operation.

#### 4.35.6.2 Worked Example Part B(I)

The calculation of the maximum membrane stress that the cracked plate can withstand is undertaken by repeating the calculation described in Part (a) for higher stresses, and plotting the resultant family of failure assessment points on the FAD. This is illustrated in Figure 12, which indicates that the failure assessment point moves from the safe and acceptable region of the diagram to the unacceptable region at an applied membrane stress of  $\sim 250$  MPa.

**Figure 12** Failure assessment diagram for semielliptical flaws ( $a = 5$  mm,  $2c = 50$  mm) in a flat plate under an increasing membrane stress. Failure predicted at an applied stress of 250 MPa.

**Figure 13** Failure assessment diagram for semielliptical flaws of increasing size in a flat plate under an applied stress of 100 MPa. Failure predicted at a defect size of approximately  $a = 18$  mm.

#### 4.35.6.3 Worked Example Part B(II)

The calculation of the maximum safe life of the component is undertaken by first assessing whether the applied stress intensity factor is greater than  $K_{ISCC}$ . The value for  $K_I$  calculated above was equal to  $14.5 \text{ MPa}\sqrt{\text{m}}$ , see eqn [21]. This is above the value of  $K_{ISCC}$  given for this material and environment combination. Therefore the dimensions  $a$  and  $c$  will both increase by  $1 \text{ mm year}^{-1}$  by SCC. The second step is to repeat the calculation described in Part (a) for defects of increasing size, and plot the resultant family of failure assessment points on the FAD.

This is illustrated in Figure 13, which indicates that the failure assessment point moves from the safe and acceptable region of the diagram to the unacceptable region at a defect size of approximately  $a = 18$  mm and  $2c = 76$  mm. As the starting flaw size was  $a = 5$  mm and the defect is estimated to propagate at a rate of 1 mm per year, this equates to 13 years of continued operation.

### Glossary

**Monocoque** A vehicle body fabricated from a single piece of material with no separate load-bearing parts.

**Electrocoating** A process for applying paint involving application of a DC potential to a submerged work piece to attract paint particles that carry an opposite charge.

**Electroendosmosis** The movement of the liquid medium of a colloidal solution towards an electrode.

**Electrophoresis** The separation of ionic molecules by their differential migration through a gel in an electric field, according to the size and charge of the molecules.

### Abbreviations

**OEM** Original equipment manufacture

**PVC** Polyvinyl chloride

the modern motor vehicle. A mild-steel car body can be exposed to strong sunlight and high surface temperatures in the summer and to freezing temperatures, surface condensation, frost, ice, and snow in the winter. Rainfall, throughout the year, wets the vehicle regularly, but may not necessarily wash it clean. The paint finish may be damaged by road stone impacts and can be attacked chemically by deicing salts and any aggressive airborne pollutants present in the local environment.

Over the past 25 years, the automotive industry has made significant advances in corrosion engineering management, by adopting an integrated approach to design, material selection, and protective coating technologies, in particular the use of multicoat paint systems and compatible sealants.

The real improvements that have been made in total vehicle corrosion protection have been reflected, most noticeably, in the longer antiperforation warranties now offered, as standard, by most of the volume car makers.

### 4.37.2 Corrosion of Automotive Bodywork

The bodywork of modern automobiles consists of separate steel panels and reinforcing sections, which are joined together by electrical-resistance spot welds

#### 4.37.1 Introduction

No other mass-produced consumer product suffers attack from its service environment as persistently as

and runs of seam welds. The resulting (monocoque) construction, which will accommodate slight movement and flexing as the vehicle travels over uneven road surfaces, contains a number of small crevices and relatively inaccessible areas. It is in these crevices and localized box sections that the likelihood of corrosion is greatest. Dirt and road salts will, over time, find their way into any unprotected crevices and structural joints. When moist, accumulations of such deposits provide a favorable environment for corrosion to occur and then to advance.

Environmental conditions have a great effect on the rates of corrosion. The rates are at their highest in damp atmospheres, because the dirt and debris present will absorb moisture from the atmosphere more readily. Salt deposits and chemical pollution cause the most rapid corrosion. Condensation and dew will favor corrosion more than heavy rain, as rain water can often wash away surface dirt and road salts, leaving a relatively clean and evenly wetted surface.

Serious corrosion of vehicle bodywork almost always starts from the inner side of the metal surface. The first sign on the outer painted surface of the bodywork is usually localized blistering and lifting of the coating system. If left to advance, the corrosion will result ultimately in perforation of the metal panel and possible structural weakening. Corrosion of the bodywork from the outside, for example, as a result of stone chipping or scratching, is usually slow to advance and may remain 'cosmetic' for a long time, as modern automotive paint systems have good adhesion to the steel surface and good anticorrosive properties. These performance qualities can limit substantially the spread of corrosion by undercutting.

Some typical examples of corroded bodywork are shown in [Figures 1–3](#).

#### **4.37.2.1 Mechanisms and the Most Common Sites of Corrosion**

The corrosion that is found most often on automotive bodywork is the result of pitting corrosion. Crevice corrosion and corrosion due to fretting may also occur, and the so-called 'waterline corrosion' can still sometimes be seen on the external bodywork of older vehicles.

Localized pitting corrosion is an electrochemical process involving differential aeration cells. In the presence of an electrolyte, current flows from one area of the bodywork which is not well oxygenated (the anode), to another region which is well oxygenated (the cathode). The corrosion takes the form

**Figure 1** Incipient panel perforation.

**Figure 2** Corrosion along a panel bend.

**Figure 3** Corrosion along a door sill.

typically of small pits on the metal surface. Once initiated, these corrosion pits may develop rapidly.

Pitting corrosion may occur wherever particles of dirt have settled on the undersides of the metal bodywork and given rise to a difference in the oxygen concentration, compared with surrounding, cleaner areas. When part of a metal surface is covered by a drop of water, for example, anodic and cathodic regions can be set up as a consequence of differences in oxygen concentrations – the area underneath the droplet is starved of oxygen and becomes anodic; adjacent areas, not starved of oxygen in this way, become cathodic. Metal wastage then occurs in the anodic areas.

When the drop of water contains dissolved salt from the roads, its conductivity is increased and the corrosion rate is accelerated. Microclimates formed within the bodywork during the service life of a vehicle will usually provide the moisture needed for such corrosion reactions to proceed.

Whenever a motor vehicle moves at speed along a wet road, spray produced by the tires is deposited on the undersides, most often in each of the wheel arches. Some wet dirt from the road may also be propelled towards the undersides of the body. This dirt may contain salt in winter months, if deicing of the road has been needed. The faster the speed of the vehicle, the less water is associated with the dirt and the more the dirt will be compacted. In addition, the more the speed of the vehicle, the less the momentum of the road dirt and the more likely it is for the road dirt to be deflected into crevices in the bodywork by the pressure eddies created around a fast moving vehicle by turbulence.

Damp, dirt, road salts, and general debris that are then thrown towards the undersides of a vehicle in this way collect not only over headlights, but also on ledges, some of which may be out of the line of any direct spray. These relatively inaccessible ledges may not then be cleaned when driving subsequently in wet conditions.

The sites on vehicle bodywork most prone to pitting corrosion include, therefore:

1. all underbody areas where road dirt can accumulate and restrict natural drying;
2. beneath mud poultrices, wherever they have formed;
3. within poorly protected (or damaged) folds and flanges of the bodywork;
4. beneath poorly adherent, but coherent, paints and protective coatings.

In vehicle bodywork, crevice corrosion can develop, in the presence of moisture, where two metal surfaces

have been joined together. The deeper part of the crevice that is formed is often starved of oxygen and so becomes anodic. Most commonly, small crevices are formed when body panels have been joined by spot welding. Over time, these small crevices fill with dirt, preventing evaporation of any moisture present and concentrating electrolyte in a small area. Corrosion may advance rapidly.

Bolted joints are also susceptible to crevice corrosion, unless the two metal surfaces can be separated from each other electrically, by insulating washers. Corrosion will again occur in the least oxygenated regions. In the case of bolted joints, crevice corrosion of the thread will then cause the bolt to seize.

Fretting corrosion (localized corrosion as a consequence of fretting) can occur in motor vehicles. Body panels and structural members in close contact with each other may be subjected to repeated vibration, as the vehicle travels along the road. While such vibrational movement is usually small, it can lead, over time, to fretting of loose particles of metal and paint coatings. If the resulting loose particles then act as abrasives, they may damage otherwise sound surfaces and lead to corrosion. Vehicle doors, bonnets, and boot lids, if too closely fitting, for example, or if distorted as the result of an accident, are susceptible to localized fretting corrosion in this way.

Waterline corrosion in automobile bodywork is sometimes referred to as dirt-wick corrosion. It can develop where condensation may be trapped and collect, within the sills, for example. The lower parts of the doors are also prone to this type of corrosion. The problem is caused usually by rain-water penetrating old window seals in car doors and then collecting in the bottom sections. If dirt and debris also accumulates in these areas and blocks the drainage holes, a moist poultice forms. Wicking action, over time, sets up an unequal oxygen concentration above and below the resulting waterline because oxygen is available freely above the waterline and is restricted below. The rate of waterline corrosion, once established, can be rapid.

Corrosion prediction and prevention in motor vehicles has been described, illustrated, and explained in detail by McArthur.<sup>1</sup>

#### **4.37.3 Advances in the Prevention of Corrosion in Automotive Bodywork**

The corrosion resistance of motor vehicles has improved markedly over the past 25 years, permitting

longer and longer antiperforation warranties to be offered by the manufacturers, currently up to 12 years.

The improvements have stemmed from significant advances in:

1. design;
2. material selection;
3. protective paint coating systems and application methods;
4. sealants and application methods.

#### **4.37.3.1 Improvements in Design**

Many of the choices made by designers of motor vehicles may impact on the susceptibility of the vehicle to corrosion. In recent years, however, corrosion resistance has assumed a much greater prominence, driven by the warranty system, and designers now recognize clearly the consumer's need not only for pleasing, modern body envelopes but also for the best possible corrosion resistance and long-term durability that are achievable commercially.

Vehicle designers, working closely with engineering support teams, now strive to reduce high stresses in bodywork panels, for example, by avoiding the deep pressings needed to produce sharp changes of curvature. Modern body shapes tend to be much smoother and more rounded than they used to be. Smooth body profiles ensure the best possible drainage of water from the surface, not only in the pretreatment and priming stages of manufacture but also in functional use. Smoother body profiles also keep to a minimum awkward corners where dirt and road salts could accumulate and ensure that if there are any unavoidable crevices, they can be reached, in subsequent manufacture, by the robots used to apply sealant.

The avoidance of contact between dissimilar metals and the ensuing risk of bimetallic corrosion on vehicle bodywork have been largely eliminated by the introduction of plastic bumpers, radiator grilles, and door handles and nonmetallic protective side trim.

Problems of bimetallic corrosion are now limited largely to the sophisticated electronic control systems which manage modern engines, regulate anti-lock braking systems, and stabilize traction.

#### **4.37.3.2 Advances in Materials**

For many years, the dominant material of construction for automotive bodywork was carbon steel. Major advances were made initially in the mid-1970s with

the introduction of precoated steels, electrogalvanized steels, and other corrosion-resistant materials. Zinc-coated steels (coated on one side only initially) were used to protect the inner surface of body panels, leaving the outer surface uncoated and available for painting.

By the mid-1980s, two-sided electrogalvanized sheet and other zinc alloy steels had become widely available and were being used to manufacture exterior body panels. By virtue of being coated on both sides, the material afforded protection not only from internal perforation corrosion but also from external cosmetic corrosion. It was the introduction of these two-sided zinc/zinc alloy materials that made extended antiperforation and cosmetic corrosion warranties into a reality.

Over the past 15 or so years, a variety of alternative nonferrous materials, predominantly aluminum alloys and plastics, have found automotive applications. Their introduction has presented new challenges. It has driven forward advances in pretreatments for mixed metal assemblies and has helped to define suitable methods of surface preparation, prior to painting plastic bumpers, for example, to color-match the rest of the vehicle bodywork. The use of plastic materials in modern automobiles is increasing, and has contributed significantly to the industry's goal of corrosion avoidance. Plastic components have allowed weight reductions to be made and, as a consequence, savings in fuel consumption and vehicle emissions. Plastic panels present their own design challenges, however, as they contribute very little to the structural rigidity of the vehicle body, as a whole.

Aluminum alloys offer two benefits over carbon steel. First, they are much lighter, and second, they are more corrosion resistant. Aluminum alloys have been used successfully by some vehicle manufacturers for the bonnets and boot lids, primarily to reduce total weight and so improve fuel efficiency.

Improvements in the corrosion resistance of exhaust systems have demonstrated most clearly the benefits of material selection. Stainless steel exhaust systems are known to have very good corrosion resistance and much improved durability. They have not been favored widely by consumers, however, as they are significantly more expensive than their carbon steel counterparts. Aluminized steel silencers, however, are now available widely and represent a good compromise: almost as good performance, at a lower cost. The clear benefit of fitting, as standard, more corrosion-resistant aluminized steel vehicle exhaust systems was advocated by Hoar<sup>2</sup> as long ago as 1971

as a relatively simple and inexpensive way of reducing the overall cost of automobile corrosion. The implementation of his advice by vehicle manufacturers, as the availability of the products increased, has been very successful.

#### 4.37.3.3 Corrosion Protection by the Paint System

The preparation and painting of new automobiles is now a sophisticated, high-speed industrial process, with vehicle bodies passing through the entire coating line in 6–10 h.

The automotive paint systems used have been developed over the past 35 years and provide, today, not only highly durable finishes but also robust corrosion protection. The extended perforation warranties (up to 12 years) offered currently by vehicle manufacturers are a reflection of the considerable advances that have been made.

A typical paint system for a new vehicle consists of:

1. a primer (applied at a dry film thickness of 18–25  $\mu\text{m}$ );
2. a surfacer (applied at a dry film thickness of 35–40  $\mu\text{m}$ );
3. an antichip coating (applied at a dry film thickness of 50–100  $\mu\text{m}$ );
4. a finish (applied at a total dry film thickness of 45–55  $\mu\text{m}$ ).

Corrosion protection is afforded primarily by the primer and intermediate coats of the paint system. The function of the finish is to provide good appearance and customer appeal as well as good resistance to weathering, surface scratching, and surface contamination.

Initial cleaning and chemical pretreatment of the vehicle body has also advanced in recent years and provides the foundation needed for the subsequent paint system.

The contributions made by metal pretreatment, primers, surfacers, antichip coatings, and underbody protection (only) to the corrosion protection of the bodywork today on new automobiles will, therefore, be considered further.

##### 4.37.3.3.1 Pretreatment

Metal pretreatment of automotive car bodies has three main purposes:

1. to remove any surface corrosion products, pressing oils, and temporary protective coatings;

2. to improve the adhesion of the subsequent primer coat to the metal surface;
3. to minimize the spread of underfilm corrosion.

The effective removal of the oils and greases used to lubricate body panels during the forming processes has improved the subsequent efficiency of modern, new vehicle coating lines substantially.

Zinc phosphate pretreatment is used almost universally in modern automotive painting plants to provide metal cleanliness and the first stage of the corrosion protection. A typical zinc phosphate process begins with multiple cleaning stages, followed by a titanated activating rinse, zinc phosphate pretreatment, and a sealant rinse. The process is completed by multiple rinses with deionized water. In total, a seven-stage process is now typical, followed by a heated (oven) drying-off stage.

The cleaning and phosphating process is carried out on a conveyORIZED system. For the cleaning step, a weakly alkaline degreasing solution of aqueous mixtures of salts, wetting agents, and emulsifiers is used. This cleaning solution is applied by a combination of spray and dip treatments, at temperatures of 40–60 °C. The most effective removal of drawing oils takes place in the dip tanks, as full immersion allows the insides of box (strengthening) sections to be reached.

Uniformity of application of the subsequent zinc phosphate conversion coating then takes place in two stages. The clean metal surface is first activated, and the layer of phosphate crystals is then built up, typically to a thickness of 1–2  $\mu\text{m}$ .

There have been a number of developments in pretreatment processes in recent years, primarily to meet the demands of mixed-metal assemblies, energy efficiency, and environmental pressures.

Significant developments have included:

1. nickel- and manganese-enriched zinc phosphates, with controlled fluoride addition;
2. lower temperature processes and chrome-free rinses, for reduced energy cost and environmental impact;
3. optimum control of process parameters through computerized instrumentation;
4. changes from spray-and-dip to full dip processes.

The benefits from these recent developments have included:

1. excellent performance under cathodic electrocoat primers;
2. good phosphate crystal morphology;

3. reduced energy consumption;
4. the requirement for a chrome post-rinse eliminated by the introduction of safer products, such as titanates.

#### 4.37.3.3.2 Priming

The function of the primer is to provide the main corrosion protection for the automotive body. Primers are generally of the 'inhibitive' type – containing anticorrosive pigments in a film-forming binder. They are required to inhibit the spread of corrosion on the metal substrate, resulting from any defects in the coating system as a whole; to have good resistance to mechanical damage (notably chipping); and to prevent the spread of corrosion from such points of damage. In order to provide these performance requirements, they must have not only good adhesion to the pretreated metal substrate but also good adhesion to the coating applied subsequently (surfacers) of the full paint system.

The significance of the priming stage in the corrosion protection of automobile bodies is reflected in the number of innovative technological developments by automotive paint manufacturers for original equipment manufacture (OEM) over the last 40 years.

With the advent of welded unit construction of car bodies (monocoque construction) in the mid-1940s, many areas of the individual units were virtually inaccessible to a spray gun, for example, the internals of strengthening cross-members and the front end near door posts. Spray application of primers was no longer feasible, therefore, and dipping processes were introduced. Initially, dipping primers were solvent-borne, but in the 1960s waterborne formulations were introduced, leading ultimately to the development of modern electrocoat primers.

In moving towards electrocoat priming, which is now the most widespread process for applying an anticorrosive primer to mass-produced, new automobile bodies, the automotive industry has progressed from dipping of car bodies up to window level (the so-called 'slipper' dip process) to full immersion dip coating which, when first used with early waterborne dip primers, resulted in unwanted runs and sags in the coating on car body panels with complex design curvature.

Electrocoat priming of automobiles began in the late 1960s. Within 5 years, almost all mass-produced vehicles were primed in this way. Electrocoat priming offered several benefits to motor vehicle manufacturers, including:

1. uniform film build (15–35  $\mu\text{m}$ ) on all surfaces in contact with the liquid primer, including areas previously difficult to coat effectively: for example, voids in box sections;
2. greater corrosion resistance from improved coverage with a defect-free film of controlled thickness;
3. a highly efficient coating process, with ca. 95% of the coating material deposited in comparison to 50–60% with a conventional dipping primer;
4. greatly reduced solvent emissions and fire hazard.

Electrocoat paints are waterborne coatings containing film-formers (binders), pigments, extenders, and additives. The resulting dispersion will deposit an organic coating on the metal substrate when a direct electrical current is passed. Dispersions stabilized by a negative charge coagulate at the anode and dispersions stabilized with a positive charge coagulate at the cathode.

To enable deposition, the vehicle body is connected to an electrode and is immersed in a tank of the coating dispersion, together with a counter-electrode. The liquid paint is circulated in the tank continuously (forced circulation) to ensure a constant supply of the primer for deposition on the metal surface to prevent the dispersion from settling and, also, to dissipate the heat generated from the flow of the electrical current. The deposition process involves electrolysis, electrophoresis, and electroendosmosis.

Initially, electrocoat primers were of the anodic type, consisting of an acidic film-forming resin solubilized with an organic (amine-type) or inorganic base. In the late 1970s, however, demands for still better corrosion protection, notably in Canada and the colder states of the United States, led to the development of cathodic electrocoating processes. In the cathodic electrocoat process, the acidic component (a carboxylic acid) solubilizes an amine salt of the film-forming resin (epoxy).

The main reasons for the rapid change from anodic to cathodic electrocoat priming were as follows:

1. improved corrosion protection (a 3–4-fold improvement, in conjunction with suitable chemical pretreatment);
2. dissolution of iron no longer being favored;
3. improved 'throwing power' (penetration and better coating of voids);
4. corrosion protection at lower film thicknesses (18–22  $\mu\text{m}$ , compared with 25–35  $\mu\text{m}$  for an anodic electrocoat primer).

There have been several generations of cathodic electrocoat primers over the last 30 years. Each new generation has been developed to meet changes in vehicle manufacturing methods and the requirements of increasingly stringent environmental legislation. The most recent formulations are now lead-free and will perform well over low nickel and chrome-free pretreatments. Primers now cure at lower temperatures (130–150 °C) and allow steel components to which plastic parts have already been attached to be co-processed.

The development of electrocoat primers has been described in detail by Ansdell<sup>3</sup> and by Vachlas.<sup>4</sup>

#### **4.37.3.3.3 Seam sealants and anticorrosive waxes**

Sealants are usually applied to specific areas of the automotive vehicle body after the electrocoat primer has been applied. Anticorrosive waxes, however, are not usually applied until the final stage of the painting process, often while the painted metal sections are still hot, in order to aid both flow and penetration into cavities and joints.

The application of sealing compounds improves considerably the overall corrosion protection of weld seams and other jointed areas. In most modern car plants, the polyvinyl chloride (PVC) or polyurethane-based sealants used currently are applied by a hot, airless spray. Application is no longer a manual process, as these specialist coating products can be applied more effectively and more consistently by robots.

Anticorrosive waxes, where they are still employed, are also applied by spray. These wax coating products are based typically on polyethylene waxes, with added thickeners and anticorrosive pigments. They are used by some vehicle manufacturers to provide additional corrosion protection, for example, inside door cavities. The waxes are inert, water repellent, and relatively impermeable to moisture.

#### **4.37.3.3.4 Surfacer**

Surfacers, sometimes referred to as primer surfacers or filler coats, continue to play an important role in automotive coating systems. They are applied not only to the exterior of the vehicle body but also underneath the bonnet and inside the boot. The vehicle body is given, therefore, an intermediate coating that provides not only an additional defense against corrosion but also protects the electrocoat primer from damage.

The main function of surfacers, however, is still to fill and smooth any unevenness in the exterior

bodywork and provide a surface which, with the minimum of sanding (none may be required), can then be coated with the topcoats of the automotive system (basecoat and clearcoat). Surfacer have evolved considerably over recent years to be compatible with new developments in topcoat technologies, meet higher performance standards, and comply with environmental requirements.

In addition to good sandability (and repair), these multifunctional coatings must:

1. possess good mechanical properties – notably flexibility and impact resistance;
2. be resistant to stone chipping, water, and moisture;
3. have good adhesion to the cathodic electrocoat primer, seam sealants, antichip coatings, and the subsequent basecoat of the finish.

Polyester resins, combined with a suitable polyurethane resin, are now recognized as the best binder systems for surfacers. The pigmented surfacer coatings are applied at a typical dry film thickness of 35–40 µm and, increasingly are now color-coded to match the color of the topcoat.

The development of surfacers has been described in detail by Ansdell.<sup>5</sup>

#### **4.37.3.3.5 Antichip coatings**

Antichip coatings are now a well-established component of modern automotive paint systems. First introduced some 20 years ago, the primary function of these softer coatings is to provide stone-chip resistance on vulnerable areas of the car body, such as door sills, the bodywork below the front and rear bumpers, the leading edge of the bonnet, and the underbody of the vehicle.

Antichip coatings are applied by spray at typical dry film thicknesses of 50–100 µm, usually ‘wet-on-wet’ and immediately after application of the surfacer. The two coatings (surfacers and antichip) are then cured at an elevated temperature (stoved), in a common process step. It follows that good compatibility between the antichip coating and the surfacer is needed, so antichip coatings are formulated with similar polyester/polyurethane resins.

#### **4.37.3.3.6 Underbody protection**

Underbody coatings are protective coatings applied, by spray, at high film thicknesses (up to 1000 µm) to the underside of finish-painted vehicles to protect the floor panels from corrosion and abrasion caused by impacts of loose road gravel and other surface debris. These coatings need, therefore, to be durable, elastic,

and to have good barrier properties. Polyurethane-based formulations have superseded the older types of rubber-based underseals.

Some vehicle manufacturers, however, now favor plastic panels over the spray application of liquid coatings for this service function.

#### **4.37.4 Concluding Remarks**

For some 30 years, innovative technology and responses to globalization and market economics have underpinned the automotive industry's successful strategies to control corrosion in motor vehicles. Globalization has accelerated the uptake of new technologies, and manufacturer's warranty schemes have given 'corrosion avoidance' an increasingly high profile in a highly competitive consumer market.

The 'corrosion avoidance' strategy has been very successful, and corrosion problems are now confined largely to the bodywork of motor vehicles over 10 years old.

Corrosion-related failures of some mechanical, electrical, and electronic components, however, continue to occur, and these parts of the supply chain are now under increasing pressure to advance their own 'corrosion avoidance' strategies to the same high level.

Each advance in 'corrosion avoidance' adds directly to the cost of a new vehicle. The most recent study in the United Kingdom into the cost of corrosion,<sup>6</sup> which was reported in 2001, estimated that,

in the United Kingdom the overall additional expenditure for improved management of corrosion by the manufacturer was £160 million in 1999. At the equivalent added cost per vehicle of £90, the potential long-term cost benefit to the purchaser is obvious.

Whatever the final outcome of the current global financial downturn, the interplay among new technology, regulatory requirements, and consumer economics will continue to exert a potent influence on the automotive industry, and its suppliers.

Corrosion management will remain a vital element of that process.

## Glossary

**Access fitting** Entry-port system for corrosion monitoring sensors, which can be inserted or withdrawn at system pressure using a heavy duty valve and retriever tool.

**Barrel** US oil industry unit for a container holding 42 US gallons, equivalent to ~159 l or ~35 Imperial (UK) gallons.

**Biocide** A chemical added to plant and pipelines systems to control and kill bacteria.

**Bragg grating** Component of optical sensing technology using fiber sensors.

**Caliper tool** Oil industry term describing a caliper measurement tool for the inspection of corrosion in down-well oil tubing, a specific version of which is the *Kinley caliper tool*.

**Corrosion allowance** Additional thickness of material provided to ensure that the wall thickness does not drop below the minimum design thickness in service.

**Couplant** Special grease or liquid (glycerin or oil) applied to the metal surface where an ultrasonic probe is applied to measure metal thickness or detect defects.

**Coupon** Strip of material that is exposed to a corroding environment to quantify the corrosion rate by weight change.

**Electrical resistance** Technique for corrosion monitoring based on the measurement of changes in the electrical resistance of metal elements to determine the corrosion rate.

**Electrochemical noise** Electrochemical technique relying on measurement and analysis of the spontaneous currents/voltages generated between electrodes in an electrolyte.

**Electromagnetic acoustic transducer** Technique for transmitting and receiving ultrasonic waves to/from the surface of a component without the requirement for contact with an external vibrating transducer.

**Fabry-Perot sensor** Interferometer using fiber optics for sensing several parameters such as temperature, strain, and acoustic waves.

**Fiber optics** Technique for sensing a number of parameters including strain.

**Fractal and neural analysis** Mathematical analysis of shapes and images.

**Galvanic probe** Electrochemical probe using two different metals electrodes for the measurement of galvanic currents.

**Intelligent pigging** Use of an intelligent vehicle (PIG) containing instrumentation that travels in the pipeline for assessing both corrosion loss and stress corrosion cracking; also referred to as inline inspection (ILI).

**Intrinsic safety** The fitting of a sensitive fuse device (zener diode barrier) to electrical equipment in plant handling flammable substances. In UK and other countries, each electrical device must be certificated by a certifying authority.

**Iron count** Oil industry term describing the total iron content in a fluid stream.

**Lateral waves** Ultrasonic waves that are compression waves propagating close to the surface of an object, which continually generate a shear wave propagating into the bulk of the object under test.

**Lorentz force** Force on a point charge due to electromagnetic fields.

**Nyquist diagram** Diagram displaying the frequency dispersion of impedance.

**Piezoelectric crystal** Substance (quartz, lithium sulfate, barium titanate) that emits ultrasonic waves when subjected to an electrical charge.

**Planktonic bacteria** Bacteria suspended in the bulk of liquid flowing in a plant or pipeline system.

**Pressure gland** Pressure seal that can be tightened to withstand defined pressures when installing corrosion probes in a system. For safety reasons, a pressure-gland system is regarded as less reliable than an access system with associated retriever tool.

**Radiography** Technique for examining materials using either X-rays or gamma radiation.

**Radio respirometry** Instrument system investigating the respiration cycle of different bacteria types.

**Raman and Brillouin scattering** Light scattering due to time-dependent density variations in a liquid medium.

**RSTRENG** Calculation to establish the remaining strength of piping or pipeline.

**Retrieval tool** High-pressure balanced tool used for the retrieval of monitoring devices when a system is under pressure.

**Robbin's unit** Unit fitted in a length of pipeline, piping, or vessel containing metal studs used for monitoring for the presence of bacteria.

**Sour systems** Term used by the oil industry to describe a system containing hydrogen sulfide.

**Sessile bacteria** Colony (or colonies) of bacteria metabolizing on the surface of a metal under scale or other deposits shielded from the fluid.

**U-bend coupon** A metal coupon bent into a U-shape and exposed to a corrodant to test for susceptibility to stress corrosion cracking.

**Ultrasonics** Technique using high-frequency sound waves to measure the thickness of material and detect defects.

Various definitions of corrosion monitoring have appeared since the adoption of industrial corrosion monitoring techniques began to gather pace, first in the USA and later in Europe. Some definitions that have appeared in the literature are as follows:

1. The systematic measurement of the corrosion or degradation of an item of equipment, with the objective of assisting the understanding of the corrosion process and/or obtaining information for use in controlling corrosion and its consequences<sup>1</sup>
2. The assessment of the degradation of a material caused through environmental, chemical, electrochemical, or biological action or reaction<sup>2</sup>
3. Any technique used to observe or measure the progress of corrosion<sup>3</sup>

The author prefers the first definition as it clearly outlines the prime objective of corrosion monitoring and provides important information regarding the benefits obtained in the operation of a corrosion monitoring program. The second definition gives some information regarding both possible corrosion mechanisms and environments. The third definition, although correct, provides no information as to the possible objectives and the advantages of online monitoring in correlating corrosion information with plant conditions and corrosion control techniques.

The ability to correlate corrosion data with operating and process conditions is a very important aspect of corrosion monitoring that differentiates it

from inspection, which provides only a snapshot of condition at the time of the inspection. However, some inspection techniques now provide continuous information that bridges the boundary between corrosion monitoring and inspection techniques. Cox *et al.*<sup>4</sup> have pointed out that traditional corrosion control and condition monitoring are still considered to be support services and have presented reasons for this, such as that those involved are mainly technical specialists and enthusiasts, who do not have production responsibility and accountability. The basic techniques of both corrosion monitoring and condition monitoring have been refined, new technologies have been added and their functionality has been augmented by the application of modern computerized data collection, evaluation, and presentation.<sup>4</sup>

Other definitions have emphasized the multidisciplinary nature of corrosion monitoring, covering a wide range of materials, measurement techniques, instrumentation, rules and regulations, standards, logistical support, data analysis communication, and management information. It has been written that if one does not measure (monitor) corrosion, one will not be able to understand it and if one is unable to understand corrosion, one will not be able to control it or improve corrosion control techniques.

**4.36.1.2 Benefits of Corrosion Monitoring**

The effective management of corrosion in organizations is essential if corrosion risks to safety, health, the environment, and economic viability are to be maintained within acceptable limit values. The wider issue of corrosion management is covered in a separate chapter in this book. Corrosion monitoring and inspection are essential processes in an overall corrosion management system that manages corrosion risks through a combination of proactive and reactive measures<sup>5</sup> that are outlined as follows:

1. Proactive measures are those in which the requirements and implementation of the monitoring system or inspection programs are identified and in place before any corrosion or deterioration has been observed, based either on the outputs of a corrosion risk assessment or on some other review/identification of areas of possible/likely corrosion.
2. Reactive measures are implemented after a problem has been identified, either as a consequence of proactive monitoring or because of an incident or the identification of a problem as a result of inspection.

Corrosion monitoring is of particular benefit in capital intensive industries such as oil and gas (production and refining), petrochemical/chemical manufacture, and electricity generation that are concerned with large volume throughputs where intervals between scheduled shutdowns are generally long and result in large financial penalties. Thus, corrosion monitoring can help to identify and control corrosion regimes that prevail during transient operating periods such as startup and shutdown. It can signal the corrosion implications of altering steady-state operating conditions such as temperature or composition beyond the original design limits. If inspections indicate that a corrosion problem has suddenly developed in service, corrosion monitoring can help to identify the causes of the corrosion damage and/or monitor the effectiveness of proposed treatments.

In several stages of oil and gas production and refining, and in utilities (boilers, cooling water systems, fire water circuits) and power generation, corrosion risk mitigation practices are based heavily on corrosion inhibitor addition. Continuous monitoring can provide criteria to optimize inhibitor dosages with resulting savings in chemical costs. Typically, a plant trial of candidate corrosion inhibitors would be undertaken following laboratory screening during which corrosion rates would be monitored to identify the most effective inhibitor and optimum dosage rates. The coupling of monitoring data output with dosing pumps could be used to automatically control the addition of inhibitors to maintain corrosion rates below specified limits cost effectively.

#### **4.36.1.3 Making a Case for Corrosion Monitoring**

To prepare a case for the introduction of corrosion monitoring, some essential information is required in the proposal. The required detail depends on the complexity and scale of the application. In some cases, the application is relatively simple as in the case of a reported increase in corrosion rate in an item of equipment that can be monitored with a few probes and standard equipment, and the case would be relatively simple and amenable to rapid implementation. However, if the application is more complex requiring installation and implementation of a major monitoring scheme in a new or operating plant, there will be a need for a detailed proposal. Any proposal should address and define some key issues.

##### **4.36.1.3.1 Objectives**

Corrosion monitoring is usually undertaken with one or more of three objectives:

1. To enable the diagnosis of corrosion problems in operating equipment
2. To monitor and control the effectiveness of corrosion risk mitigation processes such as inhibitor addition in operating equipment
3. To facilitate the scheduling of shutdowns, usually within a risk-based inspection (RBI) strategy

It is beneficial to incorporate into the proposal examples (with references) of relevant, successful industrial corrosion monitoring programs, many of which are available from the literature and other reference sources such as the internet.

##### **4.36.1.3.2 Budgets**

Budgets are necessary for the costs of equipment (plus spares), installation and operation, data reporting, and personnel. The delivery time for equipment is required to establish the timing of installation, not least for liaison purposes with maintenance at a shutdown period.

##### **4.36.1.3.3 Choice of technique**

The techniques to be adopted for corrosion monitoring and inspection should be defined, including whether invasive (penetrating into equipment/process) or noninvasive (measurements made external to equipment) and whether continuous (data available continuously from probes/sensors exposed to the corrodant) or periodic (sensors exposed to the process but which need to be extracted for analysis such as corrosion coupons or bio-studs).

Factors to be considered include the objective(s) of the proposed monitoring, the appropriateness of candidate techniques in relation to the types of corrosion expected, compatibility with any existing techniques that are used for inspection and monitoring, and the available locations for sensors and the type of instrumentation (portable or automatic) that can be employed. Uniform or general corrosion is the easiest to monitor with a wide choice of monitoring techniques. Localized corrosion has historically been more difficult to monitor in plant or in the field but recent developments in electrochemical techniques, in particular electrochemical noise (EN), have opened the door to the monitoring of localized corrosion, in particular pitting corrosion. However, few engineers receive any training in electrochemistry and they are therefore less receptive to monitoring

techniques that are electrochemically based. The electrochemical impedance spectroscopy (EIS) and EN techniques are particularly challenging in this respect and although software can convert complex responses into simple corrosion rates, the lack of understanding of the fundamental basis of the technique inhibits adoption, especially by new users and in remote locations.

Guidance on this aspect is given by Rothwell *et al.*<sup>2</sup> It has been reported<sup>6</sup> that the most successful applications are those in which an integrated system has been installed incorporating several techniques that are the most suitable and appropriate. Of course, there has to be a compromise between the number of techniques used and the total cost including purchase, spares, and operation.

#### **4.36.1.3.4 Awareness of limitations of candidate techniques**

All corrosion monitoring techniques have advantages and limitations. Invasive techniques require entries for probes and this may have safety implications depending on the type of plant. A limitation of any monitoring technique that utilizes coupons or probes is that measurements are made on sensor elements or electrodes and not the plant itself. Additionally, the metallurgical condition of the sensor elements or electrodes may not represent the plant metallurgy and temperature differences between the actual plant material and sensor elements or electrodes may be significant.

In the cases of electrical resistance (ER) or electrochemical probes, conductive films or deposits, typified by iron sulfide that may be formed in environments containing hydrogen sulfide, can interfere with operation. An additional uncertainty in the linear polarization resistance (LPR) technique is that polarization resistance ( $R_p$ ) values are based on laboratory assessment and may not be relevant for certain environments. Galvanic corrosion is very dependent on the anode–cathode ratio, which may not be simulated by the probe.

The monitoring of localized corrosion is difficult and EN is one of the few online techniques for the monitoring of localized corrosion, although LPR systems can sometimes provide a pitting tendency of the environment. However, EN requires expertise for the interpretation of the data obtained. The skills and expertise of the personnel carrying out the monitoring program have important implications in relation to some of the complex electrochemical techniques and this should be borne in mind when the program is being planned.

Although awareness of such limitations is required, they need to be put into perspective. As long as the techniques chosen have some established reliability, these uncertainties are generally accepted bearing in mind that data are unlikely to be more than  $\pm 20\%$  accurate. Of course, coupons can be used instead of probes, but although useful for verification, coupon results are also subject to errors, albeit, of a lesser order.

#### **4.36.1.3.5 Personnel management**

It is essential that the monitoring program has strong communication links with the inspection function and the corrosion engineer. In larger organizations, it is not unknown for corrosion expertise to be located remotely from the application, which can result in delays and communication problems. If either function is contracted to a third party, a communication and responsibility structure should be established. Liaison with other departments in the organization is also an essential requirement for successful operation. For example, changes in feedstock such as the source of crude oil in an oil refinery can have profound effects on corrosion behavior and all relevant functions involved with the corrosion monitoring should be advised of such changes. Likewise, inspection and allied personnel should advise operations of revised probe locations and any changes to the corrosion monitoring programs.

The corrosion monitoring program should itself be subjected to a periodic review of performance and requirements for change on an ongoing basis. The training of staff relating to current regulations, practices, and guidance is also an ongoing requirement. The availability and commitment of operating personnel are important factors here as the author has witnessed many boxes of corrosion probes lying in half-opened packing cases on the ground in desert oil installations due to nonavailability of personnel for supervision of both installation and operation.

#### **4.36.1.3.6 Data management**

The type of data required and its examination require detailed consideration at the design stage. A debate has always existed as to the value of continuous data if the outcome is vast amounts of records that are never examined in detail. The incorporation of corrosion management guidance into overall plant management provides a framework for the data required and the personnel/departments to which it should be directed. Corrosion monitoring and inspection data should be coordinated with operating/process information and evaluated by both inspection and corrosion personnel. Data handling should be standardized and available

in a computer reporting format. All the data produced should be incorporated into relevant plant/equipment records and summary reports issued to relevant functions on a quarterly basis. The equipment that is being monitored and the associated data handling system should be reviewed regularly to avoid redundancy, duplication, and/or obsolete information being retained in current records.

Failure to standardize data recording and processing may undermine seriously the effectiveness of corrosion-monitoring programs. For example, some years ago the author carried out an audit of corrosion control measures on a major railway bridge in Scotland. An extensive program of coupon monitoring was in progress. There was a vast amount of coupon records, but no standardized reporting format to describe the appearance of the coupons. When an inspector was absent and another inspector substituted, the differing coupon descriptions resulted in inconsistencies that made accurate comparisons very difficult, if not impossible. Sadly, standards and recommended practices for the systematic recording of coupon corrosion were available but were ignored.

An example where data handling was not coordinated involved the corrosion failure of an overhead line in the saturated gas plant in a UK oil refinery, resulting in a major explosion.<sup>7</sup> The refinery controlled plant degradation mechanisms using a number of measures including materials selection, inspection, sampling for corrosive agents, and corrosion monitoring. An ER probe used for monitoring had shown a high corrosion rate, but this was not followed up.<sup>7</sup> This was one of the several problems with the corrosion monitoring and inspection recording at the refinery. Individual members of the refinery's inspection group did keep records of corrosion-related incidents, but there was no central data base to hold the information.

#### **4.36.1.3.7 Legislation and standards**

Legislation regarding corrosion engineering has been produced in several countries and standards and recommended practices relating to corrosion monitoring have been issued by bodies such as National Association of Corrosion Engineers (NACE) International in the USA and the European Federation of Corrosion (EFC). The UK Health and Safety Executive (HSE) has issued specific guidance for the offshore/onshore oil industry as well as for other industries and many other professional organizations have produced published guidance relating to corrosion monitoring, the more significant of which are listed in Appendix 1. Where available, company

in-house practices should be followed in addition to national or industry standards.

#### **4.36.1.3.8 Engineering considerations**

Regardless of the type of the sensor, commercial probes are available in fixed (screw-in, flanged) or retractable forms. Various hardware systems are available for the insertion and extraction of probes online based on pressure-gland fitting via a 1-inch (25.4 mm) full-bore opening gate-valve and access-fittings used with a retractable tool and valve. Problems such as the welding of access-fitting covers for the hydraulic test after construction need to be anticipated and prevented.

For existing plants, there is usually enough in-plant corrosion experience to identify appropriate locations of sensors. For new applications, and in particular, new processes, the location of sensors can be a complicated and contentious issue. Contractors, in general, have little experience of monitoring and can be reluctant to suggest installation in case clients conclude that their designs are using materials with inadequate corrosion resistance. Clients may have to instruct contractors that a requirement exists for monitoring and define where sensors should be positioned. Discussion with other operators of similar plants can be worthwhile. Chosen locations should be verified for appropriate working. For example, it has been known for locations to be specified at heights requiring scaffolding for reading by portable instruments. The identification of the preferred sensor type to be fitted at each location should be recorded, for example, on the relevant process and instrumentation diagram (P and ID) in the process industries.

The most important consideration when selecting corrosion monitoring locations is that they sample the corrosion risk to be evaluated. For example, within crude oil and wet gas production systems, it is important to find locations where the corrosion coupon or probe will be immersed in any produced water.<sup>8</sup> In pipelines, this is typically at the 6 o'clock position on horizontal sections, because the produced water is heavier than crude oil or gas condensates. Unfortunately, many pipeline and facility engineers have installed monitoring locations on the sides of the pipeline rather than at the bottom. Although side locations provide easier access to retrieval, coupons or probes cannot provide accurate data unless the pipelines are essentially full of water.<sup>8</sup> Operator convenience must not come at the expense of valid results when selecting coupon or probe monitoring locations.

Consideration must be given also to the provision of sufficient room at the proposed location for the operation of retriever tools that require, typically, a minimum of 4–6 feet (1–2 m) clearance.<sup>8</sup>

Intrusive probes should be situated where they can remain in place for extended periods, rather than having to be removed periodically for pigging or other routine operations. Thus, intrusive probes should be installed upstream of pig launchers and downstream of pig receivers. Where this is not possible, flush-mounted probes are required.<sup>8</sup>

Instrumentation must be engineered to minimize the risk of ignition of any flammable substances that may be present from electrical sources. This is particularly relevant to the oil and gas, petrochemical, and chemical industries. This intrinsic safety is engineered by the incorporation of zener diode barriers or an equivalent electrical engineering safety system. There is no technical reason for any corrosion monitoring system not to be engineered for intrinsic safety. Assistance on these matters can be obtained from safety staff in the company. Many countries have organizations responsible for this aspect using either American or European standards.

#### 4.36.1.4 Techniques for Corrosion Monitoring

##### 4.36.1.4.1 Historical development of corrosion monitoring

It has been estimated that the worldwide market for corrosion monitoring equipment (excluding inspection) is of the order of \$25 M including ancillary fittings and associated tools. The early US manufacturers of corrosion monitoring equipment were specialty process chemical manufacturers (in particular corrosion inhibitors), who regarded monitoring as a useful adjunct to their chemical products. Instruments were marketed as providing criteria to judge the effectiveness and optimum dosage rates of inhibitors. The instrument manufacturing/supply functions were not seen as profit centers *per se* and were mostly underfinanced, and in general, unsupported at that time.

Some of the earliest applications of corrosion monitoring were in the chemical industry. In the larger chemical companies with in-house corrosion expertise, electrochemical potential measurements were used to monitor the condition of passive materials and although this technique did not provide a rate of corrosion, it did allow operators to alter process conditions to maintain passivity and prevent

serious damage. In-house developments in other techniques such as ER enabled construction of sensors/probes that were later licensed for commercial exploitation.

The conservative oil and gas industry was initially skeptical of instrumentation that claimed to provide internal corrosion rate data online. Despite the initial teething problems (selection of the wrong technique, inappropriate sensors or probes for the environment, sensors not sufficiently robust, sensors located in the wrong location), corrosion monitoring systems were slowly introduced for both existing and new plants. This took longer in Europe as most commercial monitoring equipment was of American origin resulting in long deliveries with minimal repair facilities, spares, shortages and more importantly, little if any general guidance and application advice locally.

The experiences of companies using corrosion monitoring in various industries in the UK were surveyed in 1981 and 1984.<sup>6</sup> Unfortunately, no subsequent independent survey has been undertaken and summaries of the data from the original surveys are given in **Tables 1–3**.

The 1981 survey was carried out 10 years after UK oil production had commenced and it is interesting that some of the problems identified in the 1981 survey had been considerably improved by the time of the 1984 survey. Overall, greatest success was obtained by users of integrated systems incorporating several techniques. According to survey returns, the usual package of techniques for monitoring corrosion of industrial

**Table 1** Response rate by industrial sectors in the 1981 corrosion monitoring survey

Industry	Response – no of forms/percentage	
Oil and gas production	8/22	36%
Oil treating	6/20	30%

plant at that time comprised corrosion coupons, an appropriate online probe system (either ER or LPR), and a nondestructive testing (NDT) technique, usually ultrasonics.

Since this book was last published in 1994, continuing advances in electronics, software development, and automatic data-handling have resulted in a wider range of techniques for corrosion monitoring from an increasing number of companies worldwide. In addition, much work has been carried out developing the existing monitoring techniques such as ER and LPR particularly in relation to element configuration, data processing, and measurement sensitivity. Electrochemical techniques with simultaneous monitoring of solution resistance enabling online calibration for the determination of Tafel constants are now available in commercial instrumentation. There has been considerable laboratory development of both EIS and EN. There has also been a significant development of ER technology in the form of the field signature method (FSM) that overcomes the fundamental drawback of most corrosion monitoring

techniques by measuring the corrosion of the plant component rather than of a sensor or a coupon.

Plants are now routinely fitted with corrosion monitoring equipment in order to comply not only with required company practice but also with the legislation in a number of countries that requires the adoption of appropriate corrosion measurement techniques. Service quality from corrosion monitoring equipment suppliers has improved and delivery and servicing/repair times for equipment have gradually reduced. However, the availability of skilled personnel to operate instrumentation remains a challenge, particularly for the oil/gas industry in offshore and remote desert locations. In particular, the scarcity of expertise in corrosion theory and electrochemistry has been a considerable obstacle to the application of electrochemical monitoring techniques in both field and plant.

In addition to process plant applications, more specialized applications have emerged such as the monitoring of automobile car bodies, aircraft,<sup>9</sup> concrete reinforcement,<sup>10</sup> and atmospheric corrosion.

#### 4.36.1.4.2 Coupons

Coupons are metal samples that are exposed to the corrosion environment to establish the corrosion rate. They are withdrawn from the plant at prescribed intervals and the corrosion rate is determined by gravimetric means involving weighing the coupon before and after the exposure following the removal of the corrosion products. In high temperature applications where metals are exposed to gas mixtures at high temperatures, the coupons may gain or lose weight depending on whether the corrosion products are adherent or show a tendency to spall from the coupon surface and other techniques may be required for corrosion evaluation. Coupons are often used to provide the base-line criteria in a corrosion monitoring program for comparison with instrumented techniques such as ER or the various electrochemical techniques. When confidence is established, the coupon numbers can be reduced.

Coupons are usually strips, flush discs, or cylindrical rods mounted in suitable racks or holders (**Figure 1**) that are inserted and retrieved at shutdowns, unless inserted in a bypass line or installed in operating plant using full-bore valves or a suitable high-pressure access system.

Coupons are exposed to the corroding environment for defined periods of time and should be insulated electrically from the support system. They are available from commercial suppliers in most

**Figure 1** Corrosion coupon holders and corrosion coupons (Courtesy Cormon Ltd).

materials in a variety of geometries and are usually supplied in a surface-treated condition, weighed, and stamped with an identification number. For coupons manufactured in-house at plants, it is advisable to anneal the cut coupons in order to remove residual stresses from the cutting (often guillotining) process. Coupons can be exposed to any type of corrosive environment such as liquid corrosives, high temperature gases, soils, and the atmosphere.

The corrosion product has to be removed following exposure for evaluation and guidance is provided in the chapter on corrosion testing in this book. Errors are introduced if metal is removed in the cleaning process and they are minimized by including corrosion inhibitors in the cleaning solutions. Blank coupons can be cleaned to correct for any metal loss in the cleaning process itself. Large organizations may carry out coupon evaluation in-house but corrosion inhibitor suppliers often include a coupon evaluation service as a part of the inhibitor supply contract. Independent laboratories can also carry out this procedure for the smaller company or plant.

The corrosion rate is expressed in either mm year<sup>-1</sup> (Europe/Middle East/Asia) or mils year<sup>-1</sup> (USA) where 1 mm = 39.37 mils. The penetration rate is obtained by calculating the weight loss after exposure to the plant or field environment following treatment for the removal of the corrosion products. The other factors involved are the coupon surface

area, metal density, and time of exposure and they are related as follows:

$$\text{Corrosion rate} = 10 \times \frac{W}{dAt}$$

where:

- Corrosion rate: mm year<sup>-1</sup>;
- $W$  (weight loss): g;
- $d$  (metal density): g cm<sup>-3</sup>;
- $A$  (area): cm<sup>2</sup>;
- $t$  (time): years.

Special coupons for corrosion testing of welds, crevice corrosion, and for stress corrosion testing (U-bends, C-rings) are available from suppliers or can be assembled by users and guidance on suitable designs can be found in the literature. Errors can occur with coupon evaluation, as in any monitoring technique, and these can only be avoided by familiarity with all standards, codes of practice, and guidance from fellow workers. Coupons can exhibit localized attack such as pitting and crevice attack. If excessive localized attack is present, there is no point in reporting weight loss data. Common sense will determine if localized corrosion will negate the weight loss measurement; however, the representative reporting of coupon appearance is necessary. There is published guidance on the reporting of pitting attack on coupons.<sup>11</sup>

The author has seen many examples where users of coupons have not applied a consistent system for the description of coupon appearance, resulting in meaningless records. It is very difficult to assess coupon results prepared by different personnel without a consistent system for recording coupon appearance. Familiarity with coupon evaluation literature is recommended such as that published by NACE, American Society for Testing Materials (ASTM), and other organizations.<sup>12,13</sup>

The advantages of coupon monitoring include the relatively low cost and the provision of information on forms of localized corrosion such as pitting, crevice corrosion, stress corrosion, and galvanic (bimetallic) corrosion. Although the most common form of coupon is the metal strip, there are other geometries available, including flush-discs that sample conditions at equipment surfaces including the influence of fluid flow. Coupon strips can be exposed on supports in duplicate or in multiple arrays or on coupon-ladder racks allowing a number of coupons in different materials to be exposed at a specific location.

The disadvantages include the labor intensive nature of the technique (especially for offshore application) and the averaging of readings over the exposure period, which may mask possible shorter term excursions in corrosion rate. Automatic recording can minimize this aspect, which can also be mitigated by exposing a series of coupons at one location and retrieving individual coupons at prescribed intervals.

#### 4.36.1.4.3 Electrical resistance (ER)

ER is an online, invasive technique utilizing a metal element made of the metal or alloy of interest mounted in a suitable housing, which is exposed to the corroding environment, as shown in [Figure 2](#).

The increase in ER with time is measured as the element loses cross-sectional area due to corrosion. The use of ER for measuring atmospheric corrosion rate was first suggested in 1928 by Hudson<sup>14</sup> and was in use in laboratory experiments in England in the late 1930s. The technique fell into obscurity, until in 1954 Dravnieks *et al.*<sup>15</sup> demonstrated its potential as a practical field tool. Commercial exploitation was delayed by the need for temperature compensation that was eventually provided by locating compensating resistant elements in the probe body, which were protected from the corroding environment. Early instrumentation was marketed under the trade name Corrosometer™ by Magna Corporation in the US, with the patent relating to temperature compensation.

**Figure 2** Electrical resistance (ER) probe – spiral wide tip (Courtesy Cormon Ltd).

Currently, there are many companies in many parts of the world manufacturing this type of equipment.

Elements are available in a variety of geometries including wires, tubes, and various flush designs incorporating spiral or concentric elements, as shown in [Figure 3](#). ER elements can also be fitted into special spool designs, as shown in [Figures 4 and 5](#).

The element is exposed to the corrosive environment (liquid or gas) and measurements taken at appropriate intervals. Readings can be automatic with transmission to the control room or manual with a portable reader for computer handling on return to the office. Data transmission has been carried out via satellite transmission from offshore platforms to onshore offices. The installation of a spool in a typical plant application is shown in [Figure 6](#).

The data produced average the corrosion rate between measurement intervals, although with automatic readings on sensitive elements the intervals can be very small, and correlation with corrosion mitigation systems or plant variables can be made. The presence of conducting iron sulfide in the corrosion product on the element arising from the presence of hydrogen sulfide in the corrosion environment may invalidate the measurement as iron sulfide is a conductor. However, many corrosion engineers still use ER under these circumstances by applying a correction factor or allowance. In the case of a wire element, any pitting attack will increase the measured corrosion rate but the use of tubular elements reduces this affect by increasing the surface area of the element.

ER elements need replacement when the cross sectional area has decreased by ~50% resulting in a trade off between element life and sensitivity, that is, high sensitivity results in short life, although current

**Figure 3** Electrical resistance (ER) probe – spiral flush element (Courtesy Cormon Ltd).

**Figure 4** Electrical resistance probe (ER) – ‘Ring-Pair’ spool (Courtesy Cormon Ltd).

**Figure 5** Electrical resistance probe (ER) – ‘Ring-Pair’ spool installation in plant (Courtesy Cormon Ltd).

electronic technology has improved this situation to some extent. Accuracy for the general range of ER equipment is claimed to be 0.1% for a single measurement, but this can be improved very considerably by using special equipment, details of which are available from the manufacturer’s literature or websites. It is important that the element should represent the metal or alloy of interest for the determination of corrosion rate and errors can arise in field/plant applications related to metal composition,

**Figure 6** Electrical resistance (ER) probe – fixed attachment to plant (Courtesy Cormon Ltd).

metallurgical condition of the element, and heat transfer among other factors, but the technique is well utilized in many industries, in particular the oil and gas industry.

The cost of ER hardware is similar to that of other systems and they can be operated and interpreted by most staff without undue problems. However, noninvolved staff should be acquainted with the locations and sensitivities of probes which have been known to be used as foot supports for climbing on or around the plant.

The advantages of the technique include the capture of data without plant shutdown, the availability of both portable and automatic operation, the reasonable correlation with corrosion variables and process conditions, and the assessment of the effectiveness of corrosion mitigation techniques. Special probe designs are available for use at high temperatures such as in power station boilers, in aircraft components, and in underground pipelines and for the measurement of atmospheric corrosivity.

The disadvantages include problems with conducting corrosion products in sour systems, localized corrosion that can introduce errors in interpretation, and the trade off between element sensitivity and life.

#### **4.36.1.4.4 Electrochemical techniques**

##### **Potential measurement**

Potential and its variation with time are indicators as to the condition of passive films, but corrosion penetration rates are not obtained. The hardware required consists of an appropriate reference electrode and working electrode, which can be the plant component

of interest, and a high-impedance voltmeter. This technique has been used in the chemical industry for assessing the condition of passive materials in some applications. Pioneering work on the technique by Edeleanu<sup>16</sup> demonstrated that potentials of UNS S30400 stainless steel in sulfuric acid varied with pumping speed, temperature, and the presence of impurities. Laboratory determination of polarization characteristics can identify passive and active potential ranges for a given material/environment combination.

The choice of an appropriate reference electrode is a challenge for noncorrosion aware personnel. Ideally, a reversible reference electrode such as a calomel or silver–silver chloride electrode should be used but, in practice, nonreversible electrodes can be deployed as long as they maintain a stable potential. Commercially available polarization resistance probes can be adapted for this purpose.

#### Potentiodynamic/cyclic polarization

These techniques measure the polarization characteristics of the metal–environment system of interest and laboratory procedures have been outlined and described.<sup>17</sup> Polarization curves are obtained by polarizing a working electrode potential relative to a reference electrode using external current supplied via a counter electrode in a conventional electrochemical cell arrangement. The choice of reference electrode is an issue, as in the case of potential measurement. In theory, this technique allows measurement of the Tafel constants,  $b_a$  and  $b_c$ , from the slopes of the linear portions of the anodic and cathodic polarization curves for the relevant anodic and cathodic processes that define the corrosion process. Corrosion rates can be measured by extrapolating the linear portions of the curves to intersect at the natural corrosion potential.

Cyclic polarization is a variation of the potentiodynamic technique in which the potential is reversed in the negative direction following an anodic scan. The breakdown potential in the anodic scan and any hysteresis in the anodic segment of the reverse scan can be indicative of the tendency toward pitting and crevice corrosion respectively. Guidelines for carrying out these tests are given in an ASTM standard.<sup>18</sup>

Portable commercial potentiostats are available that allow polarization measurements to be made *in situ* in operating plants. However, polarization characteristics are often relatively complex and these techniques require careful, informed interpretation and are not used routinely for corrosion monitoring.

#### Linear polarization resistance (LPR)

As aqueous corrosion is an electrochemical process, the measurement of the current involved in the corrosion reactions and the use of Faraday's Law should provide, in theory, a quantitative measurement of corrosion rate. However, it is not practicable to measure the internal corrosion current using an ammeter on the surface of a corroding metal in which the anodic and cathodic sites are inseparable. The current can, however, be calculated from the polarization characteristics of a material in an environment using the Stern and Geary relationship<sup>19,20</sup> developed from the mixed potential theory for a corroding electrode, which defines a linear relationship between applied potential and current density close to the natural corrosion potential:

$$R_p = \frac{\Delta E}{\Delta I} = \frac{b_a b_c}{2.3 i_{\text{corr}} (b_a + b_c)} = \frac{B}{i_{\text{corr}}}$$

where:

- $R_p$  is the LPR;
- $\Delta E$  (equal to  $E - E_{\text{corr}}$ ) is the potential shift from the corrosion potential,  $E_{\text{corr}}$ ;
- $\Delta I$  is the measured external current flowing due to this potential shift;
- $i_{\text{corr}}$  is the corrosion current at the free corrosion potential,  $E_{\text{corr}}$ ;
- $b_a$  and  $b_c$  are Tafel constants.

The Stern–Geary relationship is valid only for specific experimental and theoretical conditions among which are that  $\Delta E$  is small, typically  $< \sim 20$  mV. The measurements can be completed relatively quickly and are in effect instantaneous, and can therefore be utilized to control corrosion mitigation practices in operating equipment, such as the addition of inhibitors to recirculating cooling water systems or crude distillation column overheads in oil refineries.

Probes for the LPR technique are available in either two- or three-electrode versions, as shown in Figure 7, which also shows the access fitting, which is the preferred method for inserting probes into plants.

Two-electrode probes have identical metal electrodes between which the applied voltage (up to 30 mV) is applied and the resulting current measured. The applied voltage is then applied for a second time but with reversed polarity and an average is taken of the readings. A cycle time of around a minute is generally used, after which, in theory, steady state conditions prevail. In three-electrode probes, the potential difference between the reference electrode

**Figure 7** Linear polarization resistance (LPR) electrochemical probe and 'access fitting' (Courtesy Cormon Ltd).

and working electrode is sensed and an additional  $\pm 10$  mV polarization is applied. The three-electrode probe can provide measurements in more resistive solutions but has the disadvantage of measurement error if the current chosen is too large and the working electrode is polarized beyond the  $\sim 10$  mV level.

Rod-type electrodes are supplied in many metal compositions separately from the probe and electrodes are attached to threaded rods located in the probe. Probes are available in fixed (screw-in), flange fitting, retractable (pressure-gland fitted via a full-bore opening gate-valve) and in versions for commercial retrieval systems. Instrumentation is available in various forms ranging from handheld downloading devices to fully automated systems. Results are converted to penetration rates ( $\text{mils year}^{-1}$  or  $\text{mm year}^{-1}$ ) using appropriate values of  $B$  that are available from the literature for a wide range of material/environment combinations.

The key advantage of the technique is that it is close to instantaneous, giving an estimate of corrosion rate in a short time, typically several minutes, enabling rapid correlation with process conditions.

The disadvantages include the restriction of the technique to conducting solutions, although resistance compensation is available on some systems, and the requirement for values of  $B$  for the relevant reactions. Deposits on the probes can interfere with

measurements, and errors are introduced if oxidizing or reducing reactions are active that are not involved in the corrosion process. It is good practice to use other corrosion monitoring techniques in a package of techniques to validate and calibrate the technique.

#### **Galvanic current**

The galvanic current arising between two different metals can be measured using a zero-resistance ammeter (ZRA) in series between two different electrodes. The current can be related to metal loss using Faraday's Law. This is a long-established laboratory technique that has been extended into plant for the qualitative estimation of galvanic corrosion using, for example, commercial LPR probes fitted with two different metal electrodes.

#### **Electrochemical impedance spectroscopy (EIS)**

EIS is similar in approach and hardware to the LPR technique with the exception that an AC rather than a DC perturbation is applied to the electrodes at a range of applied frequencies. The resultant current and phase shift between the applied potential and resulting current are measured. The total impedance comprises contributions from the charge transfer and solution and diffusion impedances, and these can be identified separately and quantified by the use of AC impedance measurements at varying frequencies. The first AC instrument for measuring corrosion was developed by the UK Admiralty Materials Laboratory with the objective of correcting the errors involved with the LPR technique.<sup>21</sup> A fixed frequency of 10 Hz square wave was applied between the electrodes. The working electrode oscillated at  $\pm 5$  mV about a floating  $E_{\text{corr}}$  potential using an AC square wave coupled potentiostat. The measurement about a floating rest potential is a major advantage of the AC technique in systems where transients in potential would cause difficulties in measurement using a DC technique.<sup>1</sup> There is an extensive literature relating to the development of EIS as a laboratory/research tool for the investigation of corrosion.<sup>22–24</sup> Current interest is focused on the use of harmonic analysis (HA) of the response of electrodes to the application of a single frequency, from which Tafel slopes and Stern–Geary constants can be determined.

The main advantage of EIS relative to conventional LPR is that measurements at different frequencies allow corrosion rates to be determined in more resistive corrosion environments such as crude oil–water mixtures and concrete. The technique also

provides insights into corrosion mechanisms, such as whether corrosion processes are charge or mass transfer controlled and it can be deployed in operating plant using standard, commercially available LPR probes with associated access facilities.

The main disadvantage is the specialized knowledge that is required for the verification of instrument/computer outputs and the interpretation of results, which is an obstacle to the widespread deployment of EIS for industrial applications.

### **Electrochemical noise (EN)**

The EN technique involves the analysis of spontaneous potential or current transients that arise on or between corroding metal electrodes. The EN technique was first identified by Iverson<sup>25</sup> and there is now an extensive literature on applications in corrosion monitoring.<sup>26,27</sup> The theoretical background and development of EN are described elsewhere in this book. In the last edition of this book in 1994, EN applications in power generation plant, cooling water systems, and reinforcement in concrete were reported. Also, it was noted that probes containing combination elements utilizing several electrochemical techniques (AC and DC) had been developed and used for measurements in condensing acid environments.

The development of EN has progressed rapidly particularly due to developments in the electronic equipment that is able to discriminate between natural electrode current/voltage transients and electronic background noise. The interest in the technique derives partly from the prospect of a more reliable and flexible way of measuring corrosion rate but particularly from its unique sensitivity to localized corrosion processes such as pitting crevice corrosion and stress corrosion cracking (SCC) that is not available from other electrochemical techniques. EN is also much more responsive to system changes and upsets than any other monitoring technique, electrochemical or otherwise, which makes it a strong contender for corrosion/process control.

The technique does not perturb the electrodes as is the case with electrochemical techniques involving polarization but detects the natural voltages and currents that are generated on the electrode surfaces in the environment. Measurements can be made in a wider range of environmental resistivity compared with LPR. In the usual configuration, the potential noise and/or the current noise between two identical electrodes is measured. Currents are measured with a zero-resistance ammeter. Data analysis is used to determine the corrosion rate and/or the corrosion

mechanism. In theory, corrosion rates can be estimated from EN measurements in a manner analogous to LPR measurements. Corrosion rates are calculated using the so-called noise resistance,  $R_n$ , which is equivalent to the LPR polarization resistance,  $R_p$ , and is determined using the relationship:

$$R_n = \sigma V_n / \sigma i_n$$

where  $\sigma V_n$  and  $\sigma i_n$  are the standard deviations of the EN potential and current signals respectively. A variety of techniques can be used to analyze the data including the time basis of the data obtained, statistical analysis, which can provide mechanistic information, frequency domain transformation to characterize localized corrosion, fractal and neural analysis.<sup>28</sup>

An advantage of the technique is that it can be deployed in operating plants using standard, commercially available LPR probes with associated conventional access systems. However, the complex instrumentation can be expensive, and as with EIS, specialized knowledge is required for the verification of instrument/computer outputs and the interpretation and analysis of results. The technique is generally provided by specialized companies/contractors unless there is in-house expertise available in a larger company.

### **4.36.1.4.5 Field signature method (FSM)**

The field signature monitoring technique was developed originally to monitor internal corrosion of pipes and pipelines.<sup>29</sup> A length of pipeline (spool) fabricated from the same material as the parent pipeline is used as the measuring sample to which an array of sensing pins, typically ~3-mm diameter, is stud welded onto the exterior surface. A current is induced in the test spool and the electric field pattern is sensed by measuring the small potential differences among the pairs of sensing pins on the external surface. The electric field pattern depends on the geometry of the test spool and general or localized corrosion on the internal surface produces changes in the electric field pattern. By comparing measured potential differences with baseline values for the uncorroded spool, the distribution and dimensions of corrosion on the internal surface can be computed, as shown in **Figure 8**. Temperature and current fluctuation effects are compensated for. The original Norwegian patent for the system was issued in 1984 and was later licensed to Corrocean (Norway) for commercial application on a worldwide basis, who

**Figure 8** Field Signature Method (FSM) – Schematic (Courtesy iicorr Ltd.).

claimed that an accuracy of 0.1% of pipewall thickness could be obtained with a resolution of 0.025 mm for a 25-mm wall thickness. Large areas (several m<sup>2</sup>) can be monitored and smaller pin distances result in higher resolution for localized corrosion.

This method has been referred to in the literature as a variation of the ER system. There are now other manufacturers offering similar systems, one of which provides a two-part removable sensor sleeve as an option.

Initial application was directed at the oil and gas industry for the detection and monitoring of corrosion in subsea pipelines, especially for new systems, rather than retrofitting to an existing line, which would involve shutdown and additional cost. Applications in the last decade have expanded into topsides on offshore oil and gas platforms,<sup>30</sup> onshore pipelines/piping, and oil refining equipment<sup>31</sup> as illustrated in Figures 9–11.

An FSM system was fitted to an experimental pressurized pipeline loop in the UK that was used for the testing of oilfield corrosion inhibitors. The operator reported excellent results with emphasis on the accuracy achieved.<sup>32</sup> In one particular onshore oil field installation, considerable savings on corrosion inhibitor cost were made associated with an increase in the interval between inhibitor treatments of 2 weeks.

Advantages relate to the noninvasive nature of the technique, the large areas of actual plant components that can be monitored compared with conventional invasive probes, and the sensitivity that allows the technique to be used to correlate corrosion rates with process conditions such as in the case of

**Figure 9** Field Signature Method (FSM) – Installation on piping at bend/weld on piping (Courtesy iicorr Ltd.).

**Figure 10** Field Signature Method (FSM) – Installation in oil refinery (Courtesy iicorr Ltd.).

naphthenic acid corrosion in crude oil refining.<sup>31</sup> Pitting and SCC can be detected and corrosion monitoring across welds on pipeline welds has been successfully carried out in the North Sea.

Disadvantages include the high cost, which restricts the use of the technique to critical applications and the requirement for specialized data interpretation albeit enabled by custom-supplied software.

The data require careful interpretation since corrosion occurring more than 1 m either side of the sensing unit will not be detected and the generalization of the test spool performance to the system as a whole could be misleading if it has not been located where the corrosion is taking place. Concerns have been expressed relating to the use of FSM at high temperatures (e.g., 60 °C in the shade in the Middle

**Figure 11** Field Signature Method (FSM) – Installation on buried pipeline (Courtesy iicorr Ltd.).

East) and whether the sensitive electronics will survive sand and dust in desert environments, which applies to any instrumented system. However, appropriate and regular maintenance may reduce these problems.

Overall, this technique is one of the more interesting developments of corrosion monitoring technology in recent times as exemplified by the number of applications in the oil and gas industry and its progressive use and expansion into other industries.

#### 4.36.1.4.6 Thin layer activation (TLA)

TLA was developed originally for monitoring wear and erosion on metals such as in the measurement of the wear of automotive engines and the assessment of the effectiveness of various lubricants. The technique was first utilized for corrosion monitoring in 1983<sup>33</sup> and is based on the creation of a small quantity of a radioactive tracer in a metal surface (one part in  $10^{20}$ ) allowing the loss of metal due to corrosion to be measured by the loss of radioactivity. The corrosion product is required to be nonadherent for successful

application. Monitoring can be based on measurements of the loss in radioactivity level of the corroding surface or the increase in radioactivity of the corroding liquid environment unless the throughput is so high as to dilute the uptake of radioactive isotopes to levels that cannot be differentiated from background. Plant components can be irradiated, for example, on the inside surface of a pipe, or an irradiated coupon can be exposed invasively. The technique is noninvasive, measurements being possible external to equipment that contains an irradiated internal sample surface.

The requirement that samples or plant components be activated by exposure in a nuclear accelerator and the associated logistics have inhibited the widespread application of the technique, but some successful applications have been reported in subsea, water treatment, and paper-mill operations.<sup>34</sup>

#### 4.36.1.4.7 Chemical analysis

The contribution of a well-planned and executed chemical analysis program to corrosion monitoring is often underestimated. Changes in corrosivity may be determined by liquid analysis including changes in process conditions. The most important analyses related to corrosion behavior are levels of oxygen, hydrogen, chloride, trace elements, iron, manganese, corrosion inhibitor, and other treating chemicals such as biocides, oxygen scavengers, and pH. There are a variety of test papers for free water and pH monitoring and hydrogen sulfide and carbon dioxide testing can be carried out on-site. For on-site measurements, the first measurement should be the temperature.

Provision for chemical analysis should be incorporated in the design of process plant in order to give adequate coverage throughout the system, for example, in oil production from the well via processing facilities to the export infrastructure. Correlation with plant parameters such as temperatures, pressures, flow rates, and stream compositions can provide valuable information. Automatic analysis systems, especially those using ionsensitive electrodes with the recording of data, are recommended.

A special case of chemical analysis is the measurement of iron counts, the term used in the oil industry to describe the amount of the element iron in product streams. Results provide a valuable indication of corrosion if carried out on a systematic basis, such as from a reference point upstream and taking samples of fluid at a number of reference points downstream. Samples are analyzed in the laboratory and results are reported as weight of iron per volume of liquid.

Guidelines for iron analysis in oil and gas production are given in the literature.<sup>35</sup>

The loss of wall thickness is not obtained from this technique. However, continuous sampling gives results that provide a good indication of the amount of corrosion taking place, assuming that the corrosion distribution is uniform.

The disadvantages of the technique are that it is less effective for localized corrosion and that clearly the technique is invalidated if iron is already present in the process fluid, for example, in an oil formation. In this case, analysis for manganese can be substituted and results correlated accordingly.

#### **4.36.1.4.8 Hydrogen**

Hydrogen is produced from the cathodic reaction in many corrosion systems, particularly where acid environments such as acidizing fluids, sour systems, carbon dioxide, and naphthenic acids promote corrosion. The measurement of the presence and levels of hydrogen can give qualitative indications as to the amount of corrosion occurring. The historical technique for assessing the presence of hydrogen in the oil industry was to place a sample of produced fluids in an empty paint can. The appearance of blisters on the exterior of the can indicate the presence of sour water and consequent hydrogen.

Hydrogen atoms, due to their small size, can migrate easily through a metal lattice. If voids or defects are present in the metal lattice, hydrogen atoms combine to form hydrogen molecules and the continuous formation of molecules leads to increases in internal pressure, which eventually exceed the coherent strength of the material resulting in phenomena such as hydrogen-induced cracking and blistering.

Early probes were based on monitoring the accumulating pressure of hydrogen produced by corrosion. This does not provide a measurement of corrosion penetration directly. However, any increase in the volume of gas indicates that corrosion is underway. Pressure probes are still used in oil production and refining operations and can be installed using the standard access-fittings that are used for other types of invasive probe or coupon, enabling installation and retraction under system pressure. The hydrogen gas requires bleeding from the probe at regular intervals, which is a disadvantage in large oil fields. However, the organization of teams specifically for this purpose has worked well in the Middle East. An outer sheath can be welded onto a pipeline or piping into which hydrogen that is produced by corrosion of the bore diffuses. The pressure generated can be determined

with a pressure probe and this allows corrosion of the bore to be monitored noninvasively.

The electrochemical monitoring of hydrogen using Devanathan cells mounted on external surfaces using sealing systems to contain electrolytes was a later development by several manufacturers. Portable versions of the cells extended considerably the scope of this technique and provided a valuable tool for corrosion and inspection engineers. More sophisticated probes are now available that measure the hydrogen flux passing through a metal. Versions are available for both periodic and continuous monitoring and are noninvasive in application. Current instrument systems can measure hydrogen at very low levels with accompanying temperature recording and are available in various versions to fit different geometries.

A recent paper<sup>36</sup> describes the use of hydrogen permeation detection to correlate changes in operating conditions with corrosive conditions in a crude distillation column in an oil refinery. Measurements were taken over a 3-day period. During the monitoring periods, the refinery made adjustments to various operating parameters including chemical injection. The corrosion rates determined by monitoring correlated well with corrosion rates obtained from ultrasonic thickness measurements.

#### **4.36.1.4.9 Test heat exchangers and spool pieces**

In cooling water systems, test heat exchangers are often utilized for assessing the effectiveness of the corrosion inhibitor and consequent corrosion behavior of the heat exchanger tubes. These can often be supplied in the overall service package by the corrosion inhibitor supplier. The test unit includes several tubes that can be opened for visual observation and measurements taken of the corrosion rate by destructive, metallographic examination. The units can be isolated by valves allowing removal or replacement of the tubes without interrupting the operation of the cooling water system.

Small lengths of piping (~1 m in length) can be fitted to plants using appropriate flanges and provide valuable data as regards the corrosion characteristics. The spools can be removed at shutdowns or installed in bypass loops allowing more convenient removal and replacement. Caution in the interpretation of the results from bypass loops is required until confidence is obtained that the bypass line mimics mainstream conditions and that allowances are made for any differences.

#### 4.36.1.4.10 Monitoring of bacteria

Bacteria are present in some commercially important processes, including cooling water systems and nearly all areas of oil production. Detecting the presence of bacteria is essential for effective maintenance management that includes treatment with appropriate biocides. In time, bacteria develop immunity to specific biocides and the biocide type requires changing at prescribed intervals to keep bacterial growth under control. The most significant species of bacteria from the corrosion standpoint is sulfate-reducing bacteria, which consume sulfate in its metabolism, producing and expelling hydrogen sulfide, which is very corrosive and can induce cracking in steels. Bacteria can exist in the liquid (planktonic) or under scale/deposits (sessile) and this requires consideration in bacteria-monitoring programs. Techniques of monitoring include bacterial analysis (via filters), sidestreams, vessels, and specially designed corrosion coupons such as the Robbin's device that utilizes metal studs as described in the following paragraph. Note that monitoring in the fluid flow only would not detect the presence of sessile bacteria.

Testing for bacteria is expensive, tedious, and time consuming and considerable effort has been devoted to the development of spot tests that can identify the presence of bacteria within a 10–15 min period, *albeit* without the identification of the bacteria type. Rapid techniques for assessing bacteria include adenosine triphosphate photometry (ADP), fluorescence microscopy, and radiorespirometry. Standards and recommended practices are available.<sup>37–39</sup> The use of a microbiological laboratory is necessary to identify which type of bacteria is present involving transportation with sterile packaging that can be a challenge, particularly for offshore operations.

Coupons and probes (fitted with flush elements) can provide useful information regarding bacteria. The 'Robbin's device comprises a 25 mm diameter stainless steel pipe containing a series of carbon steel studs – any sessile bacteria will deposit on the studs and can be recovered and analyzed.<sup>40</sup> Variations of the 'Robbin's unit are commercially available for insertion into plant using standard access-fittings. Most companies supplying coupons and corrosion probes will be able to supply this equipment.

#### 4.36.1.4.11 Process parameters and conditions

An obvious collection of parameters that influence corrosion processes and require scrutiny but are often ignored, mainly due to communication problems,

relate to the process or the product under manufacture. The constituents of feedstocks and process streams should be regularly checked as well as operating plant parameters such as temperatures, pressures, the presences of gases, and flow rates and regimes. This is particularly relevant in gas and oil streams. A change in feedstock and/or source of supply can result in changes in corrosive properties. Sources and quality of water for injection points into the plant in oil refining should be regularly monitored.

### 4.36.1.5 Industrial Applications and Experience

#### 4.36.1.5.1 Oil and gas industry

##### Overview

The oil and gas industry is subject to many corrosion hazards in all areas of its operations. In addition to production and refining, the transportation of products is a major operation involving road tankers, extensive pipeline networks, and marine vessels, including coastal vessels and supertankers. Leakage of crude oil presents major environmental risks and leakage of highly flammable refined products can result in explosion and/or fire with consequential risks to life, and because of the scale of industry operations, major financial consequences arising from unscheduled shutdown and loss of production.

Although corrosion risks are mitigated in some areas by the use of corrosion-resistant alloys, the majority of industry equipment is constructed in carbon and low-alloy steels and corrosion inhibition is widely practiced at key stages of the production and refining operations to mitigate internal corrosion risks. The need to monitor and confirm the effectiveness of corrosion control by inhibition is one of the reasons for the industry's being a very large user of corrosion-monitoring equipment. The cost of corrosion to the industry has been estimated in numerous studies at ~40 cents per barrel, exemplified by a study of two oil fields operated by Agip in Europe.<sup>41</sup> A significant element of this cost is the expenditure on corrosion monitoring and inspection, as exemplified by **Table 4**, which shows corrosion-related costs for a major US oil field producing 270 000 bbl day<sup>-1</sup> (4% of total daily domestic US production) in 1999. The total annual monitoring costs were ~\$1 m as against the total inspection costs of ~\$3.3 m and the inhibitor costs (chemicals alone) of \$13.5 m.

Another major US field operated by the same company producing 246 000 bbl day<sup>-1</sup> reported

**Table 4** Detailed annual costs for corrosion monitoring and inspection and other related corrosion costs for one large US oil field

	Cost (\$ x thousand)
Inspection costs	
Overhead	\$492
Tangential radial tomography inspection	\$1409
Ultrasonic inspection	\$361
Other	\$1054
<i>Total inspection</i>	<i>\$3316</i>
Monitoring costs	
Coupons	\$924
Bacteria monitoring	\$13
Laboratory analysis	\$40
<i>Total monitoring</i>	<i>\$977</i>
Repairs	\$600
Engineering staff	\$1416
Corrosion inhibitor (chemical alone)	\$13533
<i>Total</i>	<i>\$19.84 million</i>

Source: [www.corrosioncost.com/pdf/oilgas.pdf](http://www.corrosioncost.com/pdf/oilgas.pdf)

monitoring and inspection costs as shown in **Table 5**. In this case, the expenditure on corrosion monitoring and inspection was the largest single item.

Although the industry is regarded as corrosion conscious with a good awareness of corrosion risks and corrosion control practices, serious and costly corrosion incidents continue to occur, for example, in production,<sup>42</sup> refining,<sup>43</sup> pipelines,<sup>44</sup> and transportation.<sup>45</sup>

The engineering design for a new oil field is based on the field fluid analysis. However, field fluid compositions can change radically as the field ages resulting, for example, in higher levels of recovered water and/or field souring (production of hydrogen sulfide at a later date after initial field production) and such factors increase the corrosion risk considerably. The historical approach that initial materials selection supplemented by in service inspection at scheduled shutdowns could be relied upon to mitigate corrosion risks was invalidated progressively by operating experience, not least European offshore experience in the 1970s, which clearly showed the inadequacy of this approach. Increased corrosion risks were usually mitigated by the introduction of corrosion inhibition with the result that online corrosion monitoring was gradually introduced by all the major operators. It came to be recognized that the use of an integrated system for corrosion monitoring, incorporating inspection data such as ultrasonic thickness measurements, was the optimum approach to ensuring successful operation.<sup>6</sup> In today's regulatory environment,

**Table 5** Costs for monitoring and inspection and control techniques for one US large oil field

Corrosion expense	Cost (\$ x thousand)
Inspection, monitoring and staff costs	\$9625
Repairs	\$1350
Corrosion inhibitor (chemical alone)	\$7200
<i>Total</i>	<i>\$18.175</i>

the authorities in many countries have introduced legislation requiring oil/gas installations to monitor corrosion, specifying the techniques to be adopted. The USA has introduced a Corrosion Prevention Act, which has the potential to dramatically improve corrosion prevention and control practices in the industry.<sup>46</sup> However, regulatory authorities are reluctant to impose requirements that might result in excessive economic penalties to business operations. For example, there has been a long debate in the USA regarding the frequency with which instrumented inline vehicles (smart pigs) should be used for pipeline inspection.

Regarding monitoring techniques, the industry has from the outset utilized coupons. These were later supplemented by ER probes that were first applied using portable instruments until automatic systems began to appear in the early 1970s. Automatic application took a long time to develop due to the high cost of special cable requirements. When LPR technology was introduced, its application was limited to cooling water systems and streams with some water content. There has always been controversy related to the use of LPR in oil/water streams, although measurements have been made in separated waters in bleed-off pots in crude distillation refinery units and some onshore pipelines. The extensive use of corrosion inhibition requires monitoring techniques that respond rapidly to assess the effectiveness of specific inhibitors and their required dosage rates, and this has provided a considerable impetus for techniques that provide instantaneous information such as EIS, EN, and FSM. Applications of FSM in particular are expanding on both onshore and offshore installations, because it provides accurate corrosion rates for the actual components that are being monitored.

Well-drilling is the first operation in producing oil or gas and can be affected by corrosion if corrosion control is inadequate. Fortunately, tubing used for

drilling can be inspected for corrosion on the surface when withdrawn from the well. However, mud-slurries that are used for the removal of scrapings from the drilling operation have to be treated with corrosion inhibitor and oxygen scavenger to counteract the ingress of oxygen into the drill stem. This operation is generally monitored by both coupons and LPR probes that can signal upsets in the corrosivity of the mud and correlation with chemical treatment. Certain dense halide brines are used to balance formation pressures during production operations, which can be corrosive due to dissolved oxygen or entrained air. Also, brines can be corrosive due to acid generation.

Seawater that is injected (squeeze) to recover oil requires treatment to remove oxygen and control bacteria to prevent souring of the formation, otherwise serious corrosion can occur. The water-injection facilities require monitoring on the manifold and elsewhere using coupons and LPR probes to confirm efficient oxygen removal by mechanical degassing and oxygen scavenging. Some operators also use galvanic probes, comprising steel and copper electrodes, which respond rapidly to the presence of oxygen.

Corrosion inhibitors are commonly added throughout the system from downhole (down the well) to the export line and to the water and gas lines downstream of the separators and monitoring is carried out at appropriate locations including wellheads, manifolds, interfield lines, separators (gas outlet, water outlet), export lines, piping, and terminal infrastructure to provide guidance on internal corrosion rates and inhibitor effectiveness. Corrosion monitoring is based mostly on combinations of coupons and ER/LPR probes as appropriate for the location. FSM, EIS, EN, and inspection techniques (including intelligent vehicles) are used selectively to supplement basic monitoring packages. In some installations, primary monitoring relies on the FSM technique if the benefits justify the higher cost.

Difficulties relate to inaccessibility, particularly for offshore pipelines and downhole. Nevertheless, coupons of various designs and caliper tools are available for downhole, albeit with some resulting drawbacks such as the removal of any inhibitor films that are overcome by increasing inhibitor dosage for short periods after the inspection. Subsea facilities present particular challenges related to accessibility and engineering, for which FSM test spools provide potential solutions.

For refineries, each unit needs a risk analysis and the crude distillation unit that provides feedstock to many other refinery units needs particular attention. Crude oil distillation units can suffer severe

corrosion, depending on the quality of the crude oil being processed. At one time, a refinery unit handled only one source of crude oil that was selected for its low corrosion risk. For both geo-political and economic reasons, refineries now buy diverse sources of crude oil on the spot market which has increased corrosion risks. The mixing or blending of corrosive crude oil with more benign crude oils is often practiced to reduce the corrosive risk. Any unscheduled shutdown of the distillation unit due to corrosion results in knockon effects on other refinery units with potentially enormous economic penalties. The top of the column and piping carryover to the coolers are vulnerable to corrosion by hydrochloric acid arising from the hydrolysis of calcium and magnesium chlorides. This is controlled by the removal of calcium and magnesium chlorides from the crude oil in desalter vessels upstream of the distillation unit and the addition of ammonia and neutralizing/film-forming inhibitors to the overhead stream. The pH of the water that separates from the overhead stream is used to control inhibitor addition, and the general target range for pH is 5.5–6.5. LPR probes are also used to monitor corrosion rates in the water stream but hydrocarbon contamination of both pH and LPR electrodes can result in errors if allowed to accumulate.

Hydrogen sulfide and naphthenic acids may also be present and can exacerbate corrosion risks. Naphthenic acids can be extremely corrosive to carbon steel at the temperatures prevailing in distillation columns. Risks are mitigated by either upgrading the metallurgy to stainless steel or adding corrosion inhibitors that are resistant to the temperatures involved.

The management of corrosion in distillation units is based heavily on hydrocarbon and water analysis supplemented by monitoring with coupons and ER/LPR probes to provide advanced warning of system upsets leading to corrosion damage. In addition, there have been isolated applications of FSM and EIS/EN for specialized situations such as corrosion inhibitor trials and the presence of naphthenic acid. Onstream, nondestructive examination is also utilized. As always, no single technique covers all requirements and a number of corrosion monitoring techniques should be used in an integrated system, consistent with the risks involved.

Bacteria present additional corrosion hazards in many areas of oil production operations and bacteria monitoring is essential for adequate control and to assess the effectiveness of the biocide addition. Onshore pipelines are monitored using both coupons and probes with flush elements, although the sensors

need to be removed before any online intelligent pigging is carried out. Sensors can also be used in bleed-off pots attached to pipelines.

Overall, corrosion monitoring has made a large contribution to the continuity of operation and safety in the industry, not only by providing data for life prediction of infrastructure but also by enabling optimal corrosion control practices based on corrosion inhibition to be identified.

### Case studies

The benefits arising from a well-planned and managed corrosion monitoring program are illustrated by the following cases:

1. *Oil refinery corrosion inhibitor validation* – Corrosion risk mitigation in crude distillation units is based heavily on corrosion inhibition, as already described. ER probes are utilized in many refining units for routine monitoring supplemented by coupons for verification where relevant. Automatic data collection offers the prospect of automatic control and Exxon carried out pioneering work in the USA in their larger refineries, closing the loop from the probe performance to automatic inhibitor control facilities.<sup>47</sup> The main objective for this work was to relieve the corrosion engineer of involvement in routine corrosion upsets (estimated at 60–70% of corrosion incidents) allowing more time for more complex corrosion problems. More recent applications have related to naphthenic acid corrosion, for which corrosion inhibitors were developed that would withstand the higher temperatures involved pending a possible future material upgrade. The data obtained were used to assess effectiveness of the candidate inhibitors and to establish correct dosage rates.<sup>31</sup>
2. *Dehydrated gas pipeline corrosion risk mitigation* – The advantages of using electrochemical techniques that enable online measurement of the Stern Geary factor ( $B$ ) have been reported.<sup>48</sup> One example relates to online, real-time monitoring techniques involving LPR, HA, and EN. Complementary information was obtained on both general and localized corrosion in a range of pipeline environments for steel and other metals. The real time measurements provided valuable information in low water-cut, dehydrated, multiphase, and vapor phase environments for both general and pitting tendencies. The provision of HA enabled measurement of the  $B$  value and improved the accuracy of the

measurements very much providing criteria for optimizing chemical treatments. Vapor phase environments typically exhibit 1–2 orders of magnitude lower general corrosion rate than found in liquid phase environments. The predominant mode of corrosion in the vapor phase has always been observed to be pitting corrosion, shown by high values of pitting factor, corroborated by visual observation. Other factors such as agitation or turbulent flow were correlated together with oxygen excursions.

The following cases highlight the importance of integrating corrosion and monitoring and inspection programs into an overall management system for managing recognized corrosion risks effectively, not least the deployment of monitoring and inspection resources to provide effective corrosion risk mitigation.

1. *Oil refinery explosion due to erosion corrosion* – In 2001, a major oil refinery in the UK, producing high-octane gasoline, experienced a severe explosion and fire in the saturate gas plant resulting from an overhead line rupture. The rupture resulted from local thinning due to erosion corrosion downstream of a water-wash injection inlet after ~13 years of operation. The injection inlet was listed on the inspection data base as in intermittent use and as a result had attracted relatively little subsequent inspection. In 2000, significant wall thinning had been identified and a full inspection of the area was scheduled for 2001. During the erection of scaffolding, the explosion occurred, fortunately on a public holiday, which minimized casualties and no personnel were killed. However, substantial damage was caused to the gas plant and a nearby unit resulting in a loss of production for several months and an increase in the global spot-price of high-octane gasoline. ER corrosion probes had been installed several years previously following receipt of specific information about the vulnerability of carbon steel pipework to corrosion in the vicinity of water injection points, but operators had failed to respond to the indications of increased corrosion in the wash-water feed pipe,<sup>7</sup> and as a result, a recognized corrosion risk was not managed effectively.
2. *Oil transit pipeline failure due to microbiological corrosion* – The Prudhoe field in Alaska is the largest US oil field representing 8% of domestic production. The field was threatened with a complete shutdown of production in August 2006 due to corrosion of a pipeline, resulting in an increase

of 2.2% in the worldwide spot price of crude oil. There are two eight mile (12.9 km) long oil transit lines in the field. The incident was a result of a leak in the 34-inch (86-mm) western transit line, constructed in the late 1970s, which resulted in a leakage of 200 000 gallons of crude oil – the largest spill in the field's history. The hole in the bottom of the pipe measured  $0.25 \times 0.5$  inch ( $6.4 \times 12.7$  mm) and the leak went undetected for several days.<sup>42</sup> The line carried hot crude oil from two processing facilities to a facility that blended natural gas liquids and crude oil from the east and west production facilities prior to delivery to the Trans Alaska pipeline. Following the discovery of the leak, the line was immediately closed and clean-up operations initiated. A return to full production was achieved in  $\sim 3$  weeks. Internal corrosion risk mitigation was based on the use of inhibitors, monitored using coupons, ER probes, leak detection systems, and NDT techniques,<sup>5</sup> including ultrasonics and radiography. The pipeline was accessible above ground excepting cased segments of piping at buried crossings. The US Department of Transportation (DOT) initiated an investigation into the leakage and required further inspection and remediation of the lines, including the running of an intelligent pig (ILI), through the western transit pipeline within 3 months. Intelligent pigging had not taken place in either transit line for several years, in contrast, the Trans-Alaska line is pigged every 14 days. The transit pipeline had been designated initially as a low corrosion risk but due to a reduction in flow rates, debris, and corrosion products that were normally passed through the pipeline deposited on the pipe allowing bacteria to develop beneath, resulting in corrosion. The loss of wall thickness in the pipeline was not identified before leakage occurred despite an extensive corrosion control and monitoring program employing approximately two hundred corrosion professionals and contractors conducting  $\sim 100$  000 corrosion inspections annually on pipeline and equipment locations throughout the Prudhoe Bay field and facilities, of which 60 000 were for internal corrosion detection.<sup>42</sup> The corrosion problems led to the issue of a subpoena requiring the CEO of the operating company, BP Exploration Alaska to appear before a Congressional Committee in order to describe the incident and its causes. The incident proved a public relations (PR) disaster for the company, which previously

had a long-standing reputation for investment in corrosion engineering and research, including corrosion monitoring activities.

#### 4.36.1.5.2 Chemical and petrochemical industry

##### Overview

In a retrospective view of the chemical process industries, examples of extreme operating conditions have been outlined by Dean<sup>49</sup> such as the high pressure used in ammonia synthesis of 272 bar (4000 psi), high temperature in ethylene production ( $1038^\circ\text{C}$ ), low temperature in hydrogen liquefaction ( $-215^\circ\text{C}$ ), corrosive environment in ammonia oxidation ( $\text{HNO}_3$ ), ammonium nitrate production (exothermic reactions), and the large volumes involved in the processing of petroleum products. Dean has identified a number of major events that have occurred and that have impacted on the chemical industry, shown in Table 6.

The effects of major disasters such as Flixborough (UK) and Bhopal (India) have resulted in increased concern for process hazards in chemical operations, which has focused attention on materials of construction, possible failure mechanisms, and the management, maintenance, and surveillance of chemical manufacturing plants. New standards have been adopted that require positive assurance that equipment is fit for service and degradation processes such as corrosion can no longer be ignored if they cause damage to the structure.<sup>42</sup> As a consequence, interest in online

corrosion monitoring has increased, in particular in devices that provide signals that can be used as control parameters.

### Case studies

The benefits arising from a well planned and managed corrosion monitoring program are illustrated by the following cases:

1. *Carbonate plant corrosion inhibitor validation* – A plant in the UK,<sup>1</sup> which had operated for many years, was producing sodium carbonate, using the same process without any serious corrosion problems. A change in a feedstock was made from a by-product of another process to a synthetic source, and laboratory tests on plant liquors indicated that there would be no change in corrosion rate. However, after ~18 months inspection confirmed that serious corrosion had started to occur and although some spares were available, there was a real possibility that production would be severely limited for several months with very serious commercial effects for both the operating company and its customers. Impurities in the original feedstock were identified as having had an inhibitive effect on corrosion. Initial tests had missed this because inhibitor had accumulated in the plant and maintained protection for a period after the feedstock change. ER probes were installed in affected parts of the plant. Some corroded areas were in vapor spaces subject to splashing so that electrochemical LPR probes could not be used directly but were installed in a bypass where continuous immersion occurred. These probes were also utilized in laboratory studies for screening replacement corrosion inhibitors. Possible inhibitors, many selected by analogy with known impurities in the original crude feedstock, were tested in the laboratory, and three were tested in plant trials. The complementary information obtained from the two monitoring techniques simplified the assessment of inhibitor behavior. The most economical inhibitor was identified and its performance monitored in plant trials. A large number of monitoring probes with facilities for automatic scanning and recording of data were used. The equipment cost was correspondingly high but this was justified by the speed with which a solution was found and implemented, resulting in the saving of several millions of pounds of potential lost production and even larger indirect cost to the customers and to their employees. The data

obtained were also of value in planning maintenance and shutdown schedules.

2. *Ammonia absorption train corrosion risk mitigation and productivity improvement* – a large coke oven plant experienced significant and unpredictable variations in corrosion rates during normal operations resulting in uncertainty as to the remaining life of the plant.<sup>50</sup> It was recognized that variations in the corrosion rate could be related to poor process chemistry control in the absorption unit, which had implications for the efficiency of ammonia removal. Both LPR and EN corrosion monitoring probes were installed and some typical data over a 1 month period are shown in [Figure 12](#).

The top trace shows weekly temperature excursions that coincided with a process circuit purging cycle. The bottom trace combines both EN and LPR results. The EN responded to pitting attack. On some excursions, increased corrosion rates coincided with the temperature excursion, but on other occasions, the corrosion rate did not increase unduly with temperature. At the start, the measured corrosion rate was reasonably low, but toward the end of the month, the rate increased to a maximum of six to seven times the background rate. Further monitoring revealed a relationship with a particular feature of the plant control involving a faulty pH sensor. Yet further work revealed that excursions in corrosion rate were linked to the molar ratio of two components in the process liquor. The results shown in [Figure 13](#) identified not only the cause of corrosion, but also that variations in the molar ratio also controlled the efficiency of the ammonia absorption process, thus enabling an increase in the productivity of the plant to be achieved.

#### 4.36.1.5.3 Power generation industry

##### *Coal fired boiler tube corrosion control*

Coal remains the most economical and widely available fossil fuel for the base-load generation of electricity.<sup>51</sup> Due to competition and the longer term requirement to minimize the production of greenhouse gases, operators are increasingly trying to maximize the efficiency of pulverized fuel-fired boilers by increasing the interval between scheduled maintenance shutdowns and operating the boilers under optimum conditions by a careful control of combustion parameters. For example, the UK Drax power station, which produces ~10% of the country's base load electricity, has increased the interval between

**Figure 12** Corrosion behavior in a coal plant ammonia absorber system. Reproduced from Cox, W. M.; Boyce, M.P.; Miyazawa, M.; Tanaka, Y. *Corros. Manage.* **2000**, May–June, 6–10.

**Figure 13** Corrosion behavior in coal plant ammonia absorber system – variations in corrosion process liquor molar ratio (upper trace) rate and corresponding transients in corrosion behavior (lower curves). scheduled maintenance shutdowns from 3 to 4 years and plans to extend this even further in the future. Examples of process improvements include changes in burner configuration, minimizing excess oxygen levels, and optimizing tube-cleaning procedures. The introduction of low  $\text{NO}_x$  burners over the past few years has produced a corresponding reduction in excess air and an increase in reducing conditions local to the burners. The reduction of excess air has helped thermal efficiency, whereas corrosion and boiler slagging rates have generally increased. Corrosion rates for furnace-walls can be extremely low

( $<0.1 \text{ mm year}^{-1}$ ) under oxidizing conditions but may increase to as high as  $\sim 9 \text{ mm year}^{-1}$  under highly reducing conditions. Historically, manual wall thickness surveys provided data for the prediction of likely tube-wall metal loss between major shutdowns. If this loss resulted in a remaining wall thickness less than an allowed minimum, then tubes were replaced, or a protective, nickel alloy weld overlay applied.

More recently, a range of specialized ER corrosion probes and corrosion scanner systems has been used for monitoring inaccessible surfaces in power stations during normal operations.<sup>51</sup> The sensing elements are welded to the external boiler wall and during the resistance measurement cycle, current is passed directly through the tube wall. The system instrumentation detects small increases in resistance at the nano-ohm level as the tube-wall loses material. Complete maps for corrosion loss can be assembled over large areas of boiler wall. A scanning system was installed in a boiler to monitor the performance of the welded overlay and confirmed that it was performing well, as shown in **Figure 14**, with very low rates of corrosion ( $<0.1 \text{ mm year}^{-1}$ ), in comparison with adjacent nonoverlaid tubing, where corrosion rates were as high as  $0.8 \text{ mm year}^{-1}$ .

In another monitoring exercise, variations in corrosion rate with the seasons were identified, the precise cause of which was not known other than that some coal stockpiles were thought to contain more moisture during the winter/spring period, as shown in **Figure 15**.

**Figure 14** Coal fired power station – monitoring of tube-wall using weld overlayed tubing – thickness trend weld overlay. Reproduced from Farrell, D. M.; Robbins, B. J.; Sikka, P.; Seaman, M. *Corros. Manage.* **2004**, May–June, 16–21.

**Figure 15** Coal fired power station – monitoring of tube-wall using weld overlayed tubing – high corrosion region. Reproduced from Farrell, D. M.; Robbins, B. J.; Sikka, P.; Seaman, M. *Corros. Manage.* **2004**, May–June, 16–21.

Depending on market conditions and power demand, power plants may be operated in two-shifting mode involving standby during night-time periods. Tube temperatures drop considerably before the plant resumes the next morning and concern had been expressed that this thermal cycling could damage the tube wall scales and accelerate corrosion. However, corrosion monitoring confirmed that this was not the case,<sup>51</sup> as shown in **Figure 16**.

#### **Flue gas outlet duct corrosion control**

Orimulsion<sup>®</sup> fuel offers power stations an economic incentive for use in industrial boilers.<sup>4</sup> The fuel consists of an emulsion of naturally occurring bitumen in water. However, the fuel has high vanadium and

sulfur contents, thus increasing corrosion risks, and produces more ash than conventional fuel. A large power boiler, fitted with a wet scrubber flue gas desulphurization (FGD) unit was using Orimulsion<sup>®</sup> as fuel and the flue gas outlet duct downstream of the scrubber suffered substantial corrosion damage resulting in heavy expenditure for repairs, lining, and maintenance. A program of online monitoring was initiated to establish when corrosion was taking place and, more importantly, under what conditions the flue gas could become condensing. As the probe metal temperature was lowered, acid dewpoint condensation corrosion took place at temperatures below 65 °C. As soon as this condition was established, very high rates of corrosion would occur on the flue

**Figure 16** Coal fired power station – monitoring of tube-wall using weld overlayed tubing. Two shifting operation and corrosion trends. Reproduced from Farrell, D. M.; Robbins, B. J.; Sikka, P.; Seaman, M. *Corros. Manage.* **2004**, 16–21.

duct walls. A short program of field trials established that continuous condensation occurred under certain firing conditions of the reheater furnace, especially if moisture removal by the mist eliminators on the outlet from the FGD system was less than optimal.

The field trials were extended to enable the corrosion surveillance instrumentation to remain in service in the plant resulting in significant operational savings, reduced maintenance costs, and the avoidance of expensive plant downtime, all of which previously had contributed significantly to the overall cost of generation.<sup>4</sup>

#### 4.36.1.5.4 Miscellaneous process industries

##### Desalination

Multistage flash distillation plants provide potable water by the distillation of seawater. These units have substantial amounts of copper alloy tubing for both heat pickup and cooling. The flash chambers that operate at a reduced pressure to obtain as much thermodynamic efficiency as possible are constructed from coated carbon steel. Corrosion of the copper alloy tubing and carbon steel chambers together with severe scaling are common challenges in these plants. Chemical treatments reduce the very severe scaling in these plants.

When the technology for multistage flash distillation was developed in the mid-1960s the copper alloy tubing selected was the same wall thickness as used for power generation. Considerable capital costs savings could be made if the wall thickness could be reduced, but there were concerns as to the robustness of the thinner walled tubing. A trial of both ER and LPR probes in a scaled-down rig gave excellent

correlation with destructive examinations of removed tubes. Both systems operated very well and were eventually used in operating plants to monitor the effectiveness of chemical treatments.<sup>52</sup>

##### Pulp and paper industry

Paper pulp manufacturing processes use very large volumes of water in paper production with many resulting corrosion problems. Some of the variables include temperature, chemical constituents, pH, concentration, size, and quality of the wood fibers. Recycling and environmental concerns may also influence corrosion performance. Conservation of water has resulted in recycling and reuse of water in closed loop systems. This has led to increases in the concentrations of dissolved solids and temperatures and changes in pH that have increased corrosion risks. Traditionally, carbon steel was the main material of construction but over the years, more stainless steel has been introduced. The types of corrosion experienced include pitting, crevice attack, SCC, MIC attack, weld corrosion, and corrosion fatigue.

Monitoring using advanced electrochemical techniques has been widely practiced in these plants. Most of the monitoring methods have been utilized, including coupons and electrical, in particular LPR, probes. EN has been successful in correlating online the effects of process chemistry on corrosion in Kraft continuous digesters.<sup>52</sup>

##### Cooling water systems

Recirculating cooling water systems using carbon steel tubes are treated with a range of chemicals including corrosion inhibitors. Open recirculating

systems present the highest corrosion risks due to oxygen pickup over the tower. These systems are treated with corrosion inhibitors and compatible biocides, and corrosion monitoring is ideal in this application. The cooling water is usually allowed to concentrate by  $\sim 2.5$  times for economical operation. Additional concentration would allow excessive chloride content with associated increased corrosion risks. The concentration is held at the given value by discharging a proportion of the water (blowdown) at prescribed intervals and fresh water makeup is added to keep volumes constant. LPR is the most suitable online technique for corrosion monitoring, combined with the use of coupons, which can be reduced in number when confidence in the LPR probes is established. Both probes and coupons are located in the hottest sections of the circuit where corrosion risks peak.

Compact control units for cooling water systems are available commercially that measure water parameters such as conductivity, and pH and incorporate suitable instrumentation for measuring corrosion, usually based on LPR. In the late sixties, a US chemical treatment company introduced a system incorporating an LPR measurement cell and facilities for activating a dosage pump if the preset corrosion rate was exceeded. Recently, a unit has been described incorporating seven different corrosion monitoring techniques (including crevice corrosion) to investigate the relationship between corrosion and water chemistry to facilitate corrosion control in a district heating project in Denmark.<sup>53</sup>

An example of the benefits of corrosion monitoring related to a recirculating cooling water system in a fertilizer plant that used river water and suffered severe corrosion arising from inadequate control and poor maintenance. The system blowdown was discharged to a treatment plant before eventual discharge back to the river. A trial was carried out with a suitable corrosion inhibitor and corrosion monitoring carried out at the exit of the hottest heat exchanger using both coupons and LPR probes. Following the verification of the LPR rates with both coupons and inspection techniques, some reduction in the number of coupons used was permitted. Corrosion rates were below  $0.25 \text{ mm year}^{-1}$  (10 mpy) for carbon steel. Bacterial monitoring was carried out using spot tests and periodic plate tests.<sup>54</sup>

#### 4.36.1.5.5 Pipelines (excluding oil and gas)

Pipelines are used for many different products other than oil and gas including raw and potable water,

seawater and treated wastes. Constructional materials include steels, cast irons, corrosion resistant alloys (CRAs), thermoplastic and reinforced polymers, and concrete. Carbon steel pipelines are often lined with cement and/or coated with organic coatings.

The London water ring main was constructed between 1988 and 1993 to supplement the existing Victorian water mains that have been badly affected by corrosion. Extensions to the new main are already in hand. Corrosion engineering and monitoring are utilized in the overall maintenance program.

In the Man-Made River project in Libya, a pipeline of combined length  $\sim 4000 \text{ km}$  has been constructed to carry well-water from the south to the main populated and industrial areas in the northern coastal area. The prestressed concrete coated pipe (4-m diameter and 7.6-m length) is reinforced with steel cabling. The pipes are protected from external corrosion using cathodic protection. Many corrosion problems have occurred with this system varying from corrosion of stainless steel components in the wells to corrosion of the steel reinforcement, which now, hopefully, has been controlled. Extensive corrosion monitoring using a number of techniques is carried out. A particular interest was corrosion failure of the prestressing wires.

#### 4.36.1.5.6 Transportation

One major international car manufacturer has used the ER system for monitoring corrosion on car bodies. Vehicles were driven through salt water on a test track to assess current corrosion control assemblies, materials, and coatings.

Generalized approaches to the corrosion surveillance of aircraft, emphasizing the training of personnel, have been reviewed.<sup>9,55</sup> The development potential of an ER system for civilian aircraft has been examined resulting in a US Air Force initiative of using ER sensors placed in susceptible areas using computer capture of data for a number of different aircraft.<sup>56</sup> In order to establish correlation between operating conditions and corrosion, the Canadian Air Force has used sensors in several aircraft to monitor operating conditions and base locations.<sup>9</sup> Naval flying operations are subject to very severe corrosive environments. The US Navy estimates that every hour of flying requires 27 h of maintenance. A miniature sensor has been developed by the US Navy that can remotely detect and monitor corrosion in inaccessible areas of aircraft, ships, submarines, and weapon containers. The sensor combines bimetallic thin-film microsensor technology with microelectronics with

radio frequency communication. The system collects and stores corrosion information that can be retrieved on demand by transmitted radio signals.<sup>57</sup>

#### 4.36.1.5.7 Nuclear waste storage

The nuclear industry has extensive interests in the corrosion of structural materials that are used for the storage of radioactive wastes, where the objective is to minimize moisture and geological storage areas are chosen on this basis. Active waste is stored in both carbon steel and stainless steel drums and considerable work is underway to investigate corrosion monitoring methods for the waste containers in order to maintain integrity prior to and during disposal. The development of an EN-based probe for monitoring nuclear waste containers has been reported.<sup>58</sup>

#### 4.36.1.5.8 Civil engineering

Corrosion measurements using the LPR technique have been reported on a historical building in Chihuahua, Mexico.<sup>59</sup> The building was a railway locomotive roundhouse built in 1910. LPR measurements were made in the building to evaluate the behavior of the metallic materials in the presence of a humid atmosphere. Test-cells were placed in several zones of the building's metallic structure. Data obtained from the *in situ* measurements showed that the corrosion rate was less than 1 mm year<sup>-1</sup>.

Probes with ER elements have been buried at various depths in concrete to monitor the corrosion of harbor jetties. One application related to naval infrastructure in US Navy dock facilities.<sup>60</sup> Electrochemical techniques for the monitoring of reinforcement in concrete have received much attention and laboratory development has been extensively reported. Advantages and limitations of electrochemical measurements for monitoring the reinforced steel have been reported by Rothman and Tullmin.<sup>2</sup> Details of other electrochemical techniques for assessing concrete reinforcement have been reported by Sykes<sup>61</sup> and Elsenor.<sup>62</sup>

#### 4.36.1.5.9 Atmospheric corrosion monitoring

Special ER probes using printed circuit sensors provide many advantages compared with the conventional coupon technique including remote data capture and overall convenience. Monitoring at specific locations (power plants and other industrial areas) for pollution type monitoring is now mandatory in some countries. An example of location atmospheric monitoring is the monitoring and inspection of radar towers located throughout the USA.<sup>63</sup>

### 4.36.1.6 Future Developments

An interesting development in an electrochemical technique relates to electrochemical frequency modulation (EFM).<sup>64</sup> In this technique, the potential perturbation signal consists of two sine waves of different frequencies and a corrosion rate can be obtained instantaneously, without prior knowledge of the Tafel constants. An advantage claimed for this method is its inherent data validation control using 'causality factors.' Another advantage claimed is that the method can be used successfully for corrosion rate measurements under various corrosion conditions. Corrosion rates obtained by EFM, LPR, weight loss, and solution analysis (atomic absorption spectroscopy) were in agreement.

There has been a significant increase in the applications of the FSM system and similar systems by other manufacturers in the past decade and this trend is likely to continue because of the advantages of FSM in relation to the accurate monitoring of plant components rather than sensors.

Closing the loop by using online monitoring signals to operate associated control systems will accelerate as new electronic and software developments occur. This is particularly relevant to the oil, chemical, and power industries. A major US company in process control has recently purchased a specialized corrosion control company offering advanced electrochemical monitoring, and this could offer significant advantages to both the manufacturer and the user. Improvements in electronics and analysis have taken their time to induce confidence in online monitoring. Also, the complexity and uncertain morphology of corrosion has not helped the adoption of the technology when compared with the conventional process control, for example, corrosion is not a defined, fixed parameter comparable to the measurement of temperature, pressure, or flow rate. A process control package that includes corrosion monitoring is an exciting prospect that provides for improved service in both hardware development and technical support.

A solicitation issued by the US DOT in 2007 invited research projects based on nanotechnology related to Internal Corrosion Direct Assessment (ICDA) in the pipeline industry. New nanotechnologies for the detection and elimination of internal corrosive species as well as determining the presence and corrosivity of water are a component of the program. In the solicitation, it was stated that currently available technologies are limited because some cannot be applied to all pipelines and others

require prior knowledge of where to locate the sensors and costly excavations to replace the sensors.

The oil refining industry<sup>65</sup> has stated the following requirements for a successful corrosion monitoring technique in their operations:

1. Sensitive and reliable;
2. Fast response time;
3. Operate in most if not all environments;
4. Must have online and remote data access;
5. Should be unaffected by iron sulfide (FeS) film formation;
6. Unaffected by noise, vibration, and temperature;
7. Compatible with local plant services.

The provision of a technique that satisfies all of these criteria is a challenging goal for the future.

## **4.36.2 Inspection**

### **4.36.2.1 Introduction**

The definition of inspection is “to look closely at or into” and an inspector is someone who carries out this function. One of the early inspectors was the wheel-tapper, employed by the railway companies, who tapped the wheels of railway carriages with a hammer at larger stations. Any cracks present in the wheel components would alter the tone of the sound reflection. These days this function is carried out at speed by a special testing vehicle fitted with transducers.

Inspection has one of two objectives:

1. To identify defects, flaws, cracks, or changes in physical properties in a component that deviate from the material specification.
2. To periodically inspect operating equipment in order to detect any onset of material degradation and/or mechanical failure, generally referred to as in-service inspection.

There has been much discussion over the years among NDT/E academics, specialists, and inspectors as to the precise definition of the terms flaw or defect. All materials contain flaws but they are significant only in relation to the extent to which they might impair the functionality of a component, not least whether the flaw (or defect) remains the same size or starts to grow in service.

Detailed background information on NDT/E can be obtained from the web sites such as the American Society of Nondestructive Testing (ASNT) and the British Institute of NDT (BINDT). In practice,

NDT/E remains a mixture of black-art and science. An important issue relating to practice is the training levels of NDT/E operatives, especially relevant due to the increasing tendency to buy in inspection services. The establishment of recognized inspection training programs has been a long and tedious process, driven by the relevant professional societies in several countries.

### **4.36.2.2 Historical Development of Inspection Technology**

Inspection has developed over the decades raging from the visual observation of mechanical parts through to the detection of the noise produced by the formation of cracks in industrial plant. Early inspection requirements were directed at moving components that endured stresses and strains particularly the engines, pumps, and compressors that were developed during the industrial revolution in the UK, not least the introduction of steam power, in the nineteenth century. The Second World War led to a massive development due to the requirements of the defense industries, particularly in the USA. Many techniques, including ultrasonics, radiography, acoustic emission (AE), eddy currents, and many others, now employed routinely in a range of industries were developed at that time. However, the new techniques were often oversold and problems with both hardware and data interpretation contributed initially to user disillusion. Confidence was restored with further development stimulated by user feedback. Later developments in electronics made a substantial contribution and further expansion, and development followed the introduction of the computer, in particular, the introduction of the laptop for inspection in the field.

A key issue in relation to the inspection of operating equipment is whether it is necessary to take equipment out of service for inspection. Offline inspection is somewhat easier to carry out than inspection when plant is operating, because equipment can be entered for appropriate inspections using the full range of available inspection techniques. Clearly, size can be an issue such as in the case of piping, but using appropriate borescopes, even small diameter piping can be examined and photographed or viewed by television.

There have been strong economic drivers to develop online inspection techniques, particularly for equipment in high capital cost plants operating for extended periods between scheduled shutdowns,

such as in oil production, oil refining, power stations, and chemical plants for which unscheduled shutdown is very costly relating to the cost of lost product. Online ultrasonic thickness measurements (UT) using portable probes were limited in the early days to temperatures that would not destroy the piezoelectric crystal in the probe. However, the subsequent development and use of special contact greases extended their use to higher temperatures. Water-cooled probes were introduced but proved unwieldy in operation and did not achieve overall acceptance. Welded UT probes were developed by the nuclear industry in the UK for the inspection of some fast reactor components that contained design features to protect the piezoelectric crystal from excessive temperature. These probes were hardwired to the control room and enabled continuous measurements of wall thickness and this technology soon found applications in the oil industry.

The development of phased arrays of UT probes mounted on a flexible mat, attached by a velcro mat that could be moved from one location to another, was a further useful development. An added benefit with this system related to its use in remote locations capturing data without visits, particularly valuable for the oil industry in dangerous locations subject to terrorist or similar threats. The development of TLA and FSM further extended the battery of available, noninvasive tools. Both are conventionally categorized as corrosion-monitoring techniques but could just as well be categorized as NDT/E techniques, because they bridge the historical boundary between corrosion monitoring and inspection technologies by providing data as to equipment condition continuously.

AE has also developed as a noninvasive, screening tool for identifying damage zones in equipment where 100% inspection would be too costly and/or time consuming. The identified damage zones can be then examined in detail online, using techniques such as ultrasonics. In-line inspection (ILI) vehicles used for pipeline inspection have also seen major development.

#### 4.36.2.3 The Need to Inspect for Corrosion Damage

There are many examples of serious incidents and accidents resulting in fatalities due to corrosion that was not detected because

1. Inspection was not carried out.
2. Inspection was inadequate.

3. The inspector was not sufficiently qualified in the techniques used.
4. Problems regarding the interpretation of the data.

An example of poor, inadequate inspection was the failure of a fairground ride in London in 2000,<sup>66</sup> in which two people were killed and a third person was seriously injured because a seat broke free and flung them through the air before smashing into a kiosk on the far side of the fairground. Examination showed that the ride was riddled with rust and metal fatigue. An inspection of the ride had been carried out 3 weeks before the accident by an independent safety inspector who had reported no defects or deterioration. It was disclosed at the trial that the inspector had two previous health and safety convictions. A subsequent inspection revealed signs of deterioration to the remaining eleven car seats on the ride. The inspector was found guilty of manslaughter. The jury called for tighter regulations covering fairground rides and the introduction of a regulatory body to ensure that inspectors received proper training. This incident emphasizes the importance of adequate training and good professional conduct.

An incident in the marine industry related to a boiler explosion on the cruise liner SS Norway (previously known as the SS France), the world's longest passenger liner carrying 3000 passengers. Within an hour of docking at the Port of Miami in 2003, a massive explosion occurred due to the rupture of one of the four boilers, fatally injuring eight crew members.<sup>67</sup> The steam penetrated the bulkheads on two further decks breaching the crew accommodation areas and seriously burning a further six crew members. A failure examination carried out by the US National Transportation Safety Board (NTSB) showed that a large section of the waterwall header had fractured and broken away. The rupture was caused by extensive fatigue cracking which had initiated at the bases of corrosion pits most likely resulting from improper water chemistry during lay-up periods. From 1990 through 2003, it appears that no NDT/E or appropriate internal visual inspections were carried out on the weld seams of the affected boiler despite a well-documented history of cracking of weld seams in two of the ship's other boilers in 1996. The ship never returned to service after the explosion and was scrapped.

Neglect of a significant corrosion risk and inadequate inspection resulted in Scotland's worst industrial disaster in May 2004, involving the deaths of nine workers and serious injuries to another

37 personnel at a Glasgow plastics factory.<sup>68</sup> Following an investigation carried out jointly by the UK HSE, prosecutors, and police, a fine of £200 000 was levied on two companies operating at the site. The investigation showed that the explosion was caused by the failure of a buried pipe carrying liquid propane fuel at the factory. A leak outside one of the buildings allowed liquid propane to go through the wall into the cellar area. The pipe had not been inspected since initial installation in 1969. All sections of the buried pipe had deteriorated and corroded, including a cast-iron bend joining two sections of the pipe. No corrosion protection system had been applied to the pipework.

Corrosion risk mitigation by inspection is given a high priority in the air transport industry. However, problems can occur and deficient inspection was a factor in the Aloha Airlines Flight 243 incident<sup>69</sup> involving crevice corrosion allowing water ingress at bonded joints in the airframe. Fatigue cracks occurred, driven by the extensive number of take-offs and landings associated with operating short flights between the Hawaiian Islands, resulting in extensive damage when part of the upper fuselage was torn off. The operating history had exceeded the recommended number of flights, which had not been accounted for by the airline and the manufacturer. Accordingly, the inspection schedule was out of synchronization with that recommended by the manufacturer. In addition, a manufacturer's recommendation of a specific NDT/E test had not been carried out by the airline.

Bridges are at risk from corrosion and inspection is vital to the mitigation of such risks. Following the collapse due to SCC of the Point Pleasant bridge in the USA in 1967, resulting in 46 fatalities, a national policy for bridge inspections was made law in 1968 and a massive inspection program instituted.<sup>70</sup> The recent collapse of the Minnesota freeway bridge in 2007 reemphasized the scale of the problem in the USA. A large number of bridges were built in the 1950s and 1960s and there will be a large requirement for inspection services over the next 20 years. The author was told that the design life of the Forth Bridge, opened in 1890 and providing the main UK east coast railway link between Aberdeen and London, was 'in perpetuity' – the only structure given this classification in the author's experience in any industrial sector. This bridge has received appropriate inspection and corrosion prevention throughout its life. However, the Forth Road Bridge, opened in 1964, has corroded main cables, which will take up to 7 years to replace. Each main cable consists of 11 618

wires and it is believed that ~90% of the wires are corroded. A massive project for inspection and renewal of the wires is expected to cost hundreds of millions of pounds.<sup>71</sup> The Severn Bridge, which provides a road crossing of the River Severn in the UK, is also reported as having cable corrosion with weight restrictions in force until inspection surveys now in progress assess the full extent of the corrosion.<sup>72</sup> The problem was first revealed by inspection in 2004. Special cable inspection techniques are urgently required for bridge suspension cables.

The marine industry relies on vessel certification as the basis for licensed operation. The Erika, a Maltese registered oil tanker on charter to total carrying a cargo of crude oil, broke in half and sank while approaching the Bay of Biscay in a severe storm, resulting in the most severe coastal pollution ever experienced in any country of the European Union. In the ensuing court proceedings, it was revealed that a previous certification authority had refused the issue of a certificate due to severe corrosion of the tanker but the owners had obtained recertification from another authority. Total was fined \$550 000 for the maritime pollution caused. Other fines were imposed for other charges relating to the incident and fines were also imposed on the certifying authority and the owners of the tanker.<sup>73</sup>

These failures occurred despite existing legislation relating to the inspection of the relevant infrastructure together with considerable guidance regarding appropriate inspection techniques and practices. Incidents and accidents continue to occur due to failure to recognize prevailing corrosion risks, poor communication, inadequate inspection, and inadequate training of those involved in plant operation and maintenance. These are essentially management deficiencies, the causes of and remedies for which are covered in a separate chapter in this book.

#### 4.36.2.4 Inspecting for Corrosion Damage

Inspection for corrosion damage, or other service deterioration, developed at a later stage on the inspection technology timeline. NDT/E techniques were originally targeted at material defects and manufacturing faults, but as the technology developed, attention was extended to material degradation in service. Several established NDT/E techniques were identified as having potential for the inspection of corrosion including radiography, ultrasonics, and eddy current.

NDT/E as applied to corrosion inspection has the two main objectives of detecting, and if possible,

dimensioning corrosion. Inspection staff is not always familiar with all of the many forms of corrosion and good liaison is required between the inspection function and those engaged with corrosion control. General or uniform corrosion is the easiest type of corrosion to detect and measure. Using simple thickness meters, the remaining wall thickness can be measured. For example, subsea pipelines have been inspected by clamping a raster assembly developed by the Danish Welding Institute on the pipeline in which an UT probe assembly can traverse the full circumference of the line. Robotic crawlers can carry UT probes for the inspection of the large storage tanks used by the oil industry. The FSM system has not only been applied for general corrosion but also at a discrete area such as welds.

Some forms of localized corrosion, such as pitting corrosion, proved particularly difficult to resolve with the early ultrasonic instruments and problems are still reported in this respect.<sup>74</sup> The detection of cracks, in particular stress corrosion cracks, was of particular interest to the nuclear power, oil/chemical, and pipeline industries. These are invisible to the naked eye until failure occurs but can be detected using ultrasonics and AE. For pipelines inspection, ILI vehicles are now able to detect cracks as well as reductions in wall thickness, as described in a later section.

Inspection techniques used to detect defects in manufactured products, in particular ultrasonics and eddy currents, have been adapted for the detection of various corrosion types. For example, nonferrous heat exchanger tubing has long been inspected with eddy currents to detect manufacturing flaws (pin-holes) and the technique has been adapted to inspect *in situ*, offline, for corrosion defects that may have developed in service tubing.

Although some of the oldest techniques such as visual examination and mensuration are restricted to shutdown periods, other techniques such as ultrasonics, radiography, and AE can be used online. On-site inspection does not always have the precision associated with manufacturing or workshop conditions but good correlation can be obtained when monitoring and inspection data are compared in a well-organized and integrated inspection and corrosion monitoring program. Choosing the right techniques for inspection is a challenge and generally benefits from experience.

Practical problems inevitably arise and have to be overcome. Lack of access to equipment, in relation to not only the height (requiring scaffolding) but also

the close proximity of nearby equipment, can cause problems. In circumstances where access for inspection is completely restricted, corrosion risks have to be mitigated by upgrading materials in the design or at shutdown. The presence of very thick rust can prevent the transmission of ultrasonic waves for single-point ultrasonic measurements in particular. High temperatures can degrade the piezoelectric crystal in the probe and may require the use of high temperature greases and special probe designs.

Inspection programs are now routinely planned and managed as key components of corrosion management and RBI programs, the development of which are described in separate chapters in this book.

#### 4.36.2.5 Inspection Techniques for Corrosion Inspection

##### 4.36.2.5.1 Visual inspection

A properly executed visual inspection should accomplish the following:

1. Assist in failure analysis.
2. Indicate the need for further exploration.
3. Help to define the search area if further exploration is warranted.
4. Suggest techniques for further exploration.
5. Help to determine the measures needed to prevent or minimize the recurrence of damage.
6. Reduce the possibility of installing faulty fabrications by ensuring that the right materials and fabrication procedures are used and that workmanship is of the proper quality.

Visual observation can be carried with or without optical aids. Typical signs of damage include rust staining, bulging, cracked or distorted coatings/insulation, and hot-spots that are indicative of possible corrosion damage. The value of visual observation cannot be overemphasized as long as the potential limitations of direct eye observations are recognized, including the need for access, tiredness, fatigue, and variability. Simple magnifiers can be utilized ranging to more sophisticated optical equipment using fiber-optic (FO) endoscopes (borescopes), which are used for inspection in restricted areas. These devices can be fitted with cameras or TV cameras and lengths of flexible conduit can be fitted together for the inspection of remote areas and are extensively used for inspection purposes in boilers, buildings, aircraft engines, and process plant. Self-propelled versions of robots with FO equipment attachments and attached umbilical (for power and controls) are used for the

inspection of offshore risers, terminal hoses, and short-length pipelines. The introduction of digital cameras has made a major contribution to record keeping and communication purposes. Internal corrosion inspection is generally confined to scheduled shutdown periods, but the examination of external corrosion, often related to coating breakdown, can be carried out when the plant is operating, provided access is available.

#### 4.36.2.5.2 Ultrasonics

##### *Principles*

This is one of the most important techniques for corrosion inspection, in particular, for the measurement of metal thickness. Instrumentation varies from simple thickness meters using a single portable ultrasonic probe to more complex equipment using probe arrays with phased-firing probes.

Mechanical vibrations can be propagated in solids, liquids, and gases. If their frequency is within the approximate range of 10–20 000 Hz, the sound is audible. Above ~20 000 Hz, the waves are referred to as ultrasound and their application for measurement as ultrasonics.<sup>75</sup> The waves are produced by a piezoelectric crystal that is mounted in a suitable probe (holder or an array assembly) and when excited by an electric current, transmits a high-frequency sound-wave. Ultrasound waves have different wavelengths in different materials. The waves arise because of the elastic properties of the material under test and are due to induced particle vibration in the material. If the particle motion is along the line of direction of travel, the resulting wave is called a compressional or longitudinal wave, which can be propagated in solids, liquids, and gases.

It is possible for the particle movements in solid materials to be at right angles to the direction of travel, in which case the waves are called shear waves. The velocity of these waves is around half of that of longitudinal waves. Head waves are shear waves longitudinally polarized that are produced when a wave passes along a free surface at a velocity greater than the bulk wave velocity in the material. Such a wave on a surface or down a crack face converts to shear waves. Other types of surface waves such as Rayleigh and Love waves can be generated in solid materials but are beyond the scope of this chapter.

In the pulse echo system, an electrical pulse is applied to the transmitter probe, producing a short ultrasonic pulse, which is propagated into the material through a couplant layer.<sup>75</sup> The same pulse triggers a timebase generator so that the pulse of

ultrasound starts to move through the inspected component at the same time as a spot starts to move across a cathode ray tube (CRT) display screen. Variations in voltage at the transducer due to the ultrasonic wave are passed to the amplifier and applied to the Y-axis of the CRT to produce a transmission signal that represents the shape of the generated ultrasonic pulse. The spot continues to move across the screen of the CRT as the sound pulse travels through the component until the electronic pulse reaches a reflecting or scattering surface. In the case of thickness measurement, this would be the opposite surface of the equipment wall. The basis of ultrasonic thickness/depth measurement and some special probes for the purpose are illustrated in [Figure 17](#).

Various types of ultrasonic scans can be created and viewed on a CRT, as follows:

1. A-scan – a linear timebase on the x-axis and ultrasonic signal amplitude on the y-axis is the simplest and commonest, displaying amplitude versus time of flight at a location.
2. B-scan – the apparent size and position of defects is shown on a cross-sectional plane, normal to the surface on the line of the probe scan.
3. C-scan – a two-dimensional display of the test surface in plane view is shown. The probe is scanned mechanically over the surface in a regular raster and the defects are shown as bright patches in their correct plan positions (widely used in immersion water tanks) providing a radiograph type image.
4. D-scan – is a two-dimensional display of a cross-section of the specimen along the line of the scan.
5. P-scan – was designed by the Danish Welding Institute for weld inspection, which produces a simultaneous display of A and B scans.

The various scans are illustrated in [Figures 18 and 19](#).

##### *Types of probe*

There are different types of ultrasonic probes, depending on the objective of the inspection. The most basic probe contains a single transmitter crystal and requires another probe placed on the opposite surface to receive the compression sound wave. Such an assembly would be used, for example, for the detection of defects in a cast ingot of metal. Two crystals, transmitter, and receiver, can be mounted in a single hand-held probe connected to a portable instrument that allows the measurement of metal thickness from the external surface of the metal component under inspection, such as piping or a process

**Figure 17** Ultrasonic thickness/depth measurement.

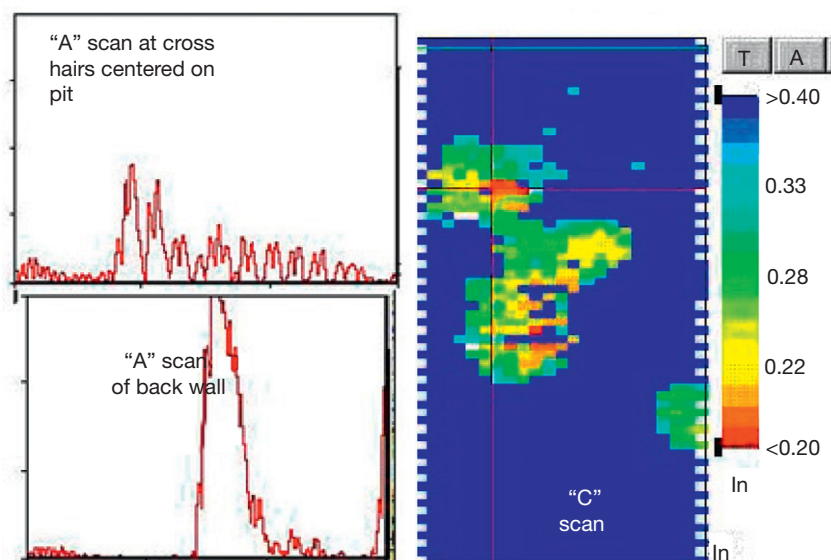

**Figure 18** Types of ultrasonic scan: A Scan amplitude versus time of flight at a location. B Scan time of flight versus distance along a transverse scan line. C Scan amplitude or time of flight versus location in scanned area. D Scan time of flight versus distance along a longitudinal scan line.

vessel. The interval between the pulses is displayed digitally, after conversion to a thickness scale using the ultrasonic velocity in the material being tested. The probe is placed on the metal surface and the reading taken. Paint layers, if present, do not generally impede the transmission of the ultrasound waves.

If surfaces are thermally insulated, cutouts can be provided at locations that are likely to be vulnerable to corrosion.

Shear probe assemblies transmit shear waves at different angles to those that transmit at  $90$  degrees to the metal surface. As in the case of compression

**Figure 19** Automated ultrasonic corrosion mapping by the computer control, processing, storage and imaging of ultrasonic signals, courtesy Matrix inspection & Engineering Inc.

probes, either separate or combined transmitter and receiver probes can be used. These angled probes are used commonly for the detection and sizing of crack like defects and weld defects and scanning with angled probes allows defect location/sizing in inaccessible locations. Conventional probes require couplants (grease) for the transmission of ultrasonic waves into the material undergoing inspection to avoid any impedance (blockage) of the ultrasound by an air gap.

Multiprobe (array) systems were developed using computers to process readings from twenty-four probes or more mounted on a single, wrap-around mounting mat, which can be moved around various locations in the plant. There are other forms of arrays such as those mounted on a wheeled trolley that is used to monitor the floors of above-ground storage tanks, now largely replaced by trolleys using the magnetic flux system that does not require water jets for coupling and can tolerate the thicker protective coatings used in tanks. Special assemblies have been developed for certain industries such as the nuclear, oil, and power, industries.

#### **Specialized ultrasonic systems**

An ultrasonic internal rotary inspection system (IRIS) for the offline inspection of heat exchanger tubes is available commercially and is widely used. Ultrasonic waves are directed at 90 degrees onto the inner surface of the tube using a 45-degree rotating

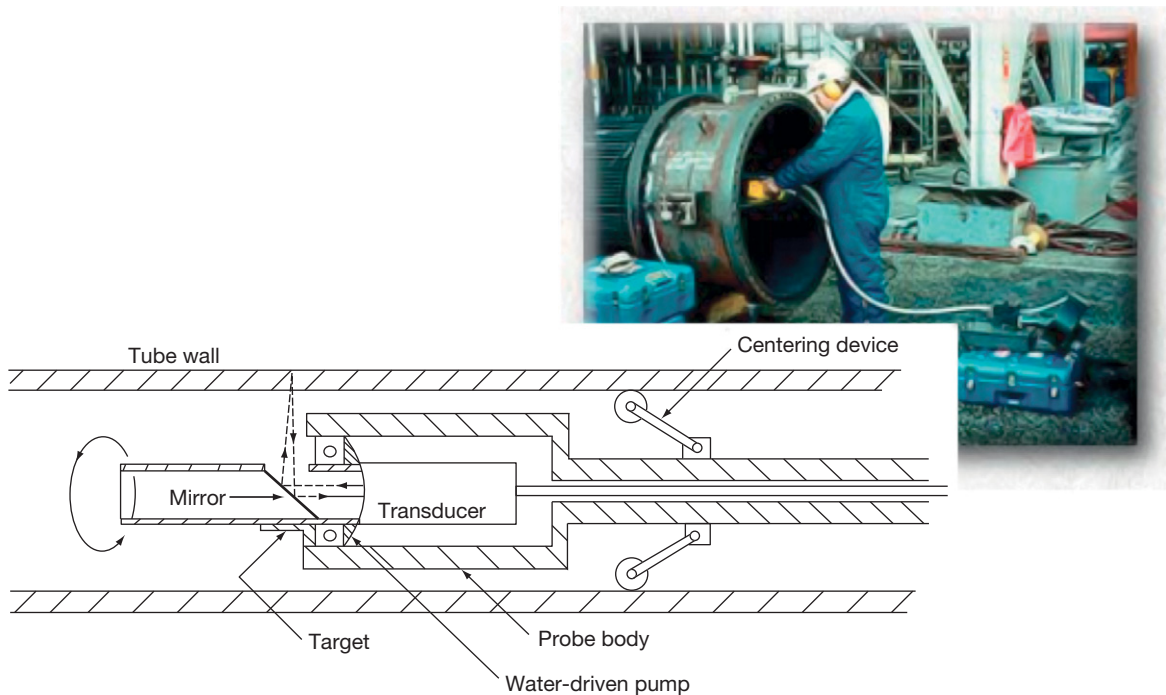

mirror reflector, as shown in [Figure 20](#). Internal and external wall thinning or pitting can be detected, located, and size estimated. This method has a number of advantages over the older eddy current technique for tube inspection, for example, that tube surfaces under baffles can be inspected, but is considerably slower and the two techniques are, to some extent, complementary.

Long-range ultrasonic transmission (LRUT) has been developed to examine piping for corrosion or erosion. One development consists of a phased array of transducers where the ultrasound is focused on a specific area along the pipe and around its circumference. Three different wave modes are used and propagation distances depend on several factors such as pipe geometry, contents of pipe, and coating and insulation present. However, in general situations, it is not unusual to obtain a range of 30 m (100 ft) in either direction from the transducer. Both internal and external corrosion can be detected, but the method is unable to distinguish between them. Pipe diameters over 50 mm can be inspected. The technique has shown particular promise for the detection of corrosion under insulation (CUI), which is a major problem in industrial plant as described in the chapter on the management of corrosion in the chemical/petrochemical industries in this book. Inspection for CUI is an expensive and tedious operation usually requiring the removal of the insulation for visual inspection. LRUT offers the prospect of inspection

of relatively long lengths of insulated piping with only limited, local insulation removal,<sup>76</sup> as illustrated in Figure 21.

Electromagnetic acoustic transducer (EMAT) systems were developed by the nuclear industry. The probes propagate Lorentz waves in a magnetic

field and depending on the orientation of the force vector, different ultrasonic wave types can be generated into a metal surface without the need for close contact between the probe and the metal surface under inspection. Both shear and compressional waves can be generated depending on the orientation

**Figure 20** Ultrasonic IRIS for heat exchanger tubing using a probe with a 45° rotating mirror that reflects the ultrasonic beam into the tube wall at 90° to the wall allowing internal/external thinning or pitting to be detected, located, and size estimated.

**Figure 21** Long range, guided ultrasonics for the detection of wall thinning due to internal or external corrosion. Rings of piezoelectric transducers, clamped around a pipe, transmit low frequency pulses in both directions. The signal obtained, amplitude versus distance along pipe, is similar to A scan and can detect over distances up to ~30 m in pipes, diameter >50 mm, wall thickness up to 40 mm. Courtesy of The Welding Institute (TWI).

of the magnetic field. There is no need for an external vibrating transducer and coupling. A stand-off from the surface of  $\sim 2$  mm can be achieved and therefore thin layers of rust or oxide scales can be left as these do not present a barrier. For pipe inspection, a transducer transmits UT signals around the pipe circumference as a self-propelled scanner is carried along a pipe. Up to 500 m of pipe can be inspected in a day and the technique can detect corrosion damage and provide quantitative thickness data.

Time of flight diffraction (TOFD) was also developed by the nuclear industry and is now used in a number of industries. This system has proved useful for assessing in service the preferential corrosion and/or erosion loss at the roots and heat-affected zones of welds. Separate transmitter and receiving probes are placed at an equal distance from the center of the weld. Ultrasound is transmitted at the appropriate angle into the weld by the transmitter probe and at any corrosion (crack), some of the energy is diffracted at its edges and detected by the receiving probe. As the sound strikes the tip of a crack or flaw, this acts as a secondary emitter, which scatters sounds in all directions, some in the direction of the receiving probe. A lateral wave (traveling at the same velocity as the compression waves) is transmitted to the receiver. The time difference between the lateral wave and the diffracted signal from the flaw or crack provides a measure of its distance from the scanned surface. The probes can measure the arrival time of ultrasound diffracted from the upper and lower extremities of a flaw or crack. The technique is useful for monitoring flaw or crack growth provided the variables are closely considered. A variety of systems are available ranging from manual scanning through to fully automated systems. A scan speed of  $50 \text{ mm s}^{-1}$  is claimed for automated systems. The comprehensive coverage afforded by the wide beams used for TOFD inspections makes it much less dependent on probe position and defect orientation than conventional pulse echo techniques.<sup>77</sup>

#### **4.36.2.5.3 Radiological techniques**

##### **Principles**

Since the discovery of X-rays in 1895, there has been extensive use of ionizing radiation for the NDT/E of materials as well as human beings.<sup>75</sup> X-rays are a form of electromagnetic radiation and have wavelengths that allow them to penetrate all materials with partial absorption during transmission. They include a fairly wide waveband of radiation from  $\sim 10$  nm, usually

called soft X-rays, which will penetrate only solid materials of very small thickness, to  $\sim 10^{-4}$  nm, often called high-energy or hard X-rays, which will penetrate up to  $\sim 500$  mm steel. Gamma rays emitted by radioactive substances such as cobalt-60 can exist over a similar wavelength range and are also widely used in industrial radiography. Neutron and protons have also been used for industrial radiography. Radiographs can be taken using portable X-ray machines or for thicker sections, it may be necessary to use radioactive source such as cobalt-60, iridium-192, or cesium-137. Radiography is very useful for confirming and quantifying the presence of corrosion detected by other inspection techniques. However, ionizing radiation can cause damage to living tissue, and therefore, appropriate personnel protection is essential and screening is required as dictated by the relevant legislation pertaining to radiation protection in different countries.

The recording of radiation is carried out using radiographic film or intensifying screens or fluorescent screens. Computer displays are common for displaying radiographic information. No waiting time is required and there is no requirement for photographic laboratory facilities.

##### **Portable systems**

Portable X-ray machines are quite small and can be taken around the plant fairly easily. The instrument consists of a filament (for the provision of electrons – a cathode), a target, the anode, a high voltage supply and a containment to enable the anode and cathode to be supported in a very high vacuum.<sup>75</sup> Developments include nonfilament tubes, where the filament is located in a recess in the cathode focusing cup, which helps to produce a narrow, well defined beam of electrons on the anode. The electron beam can be focused with electron lenses, to produce microfocus X-ray tubes. These developments have led to smaller, more robust X-ray tubes compared with the early glass-envelope design. The portable X-ray machines do not present a hazard above normal safeguards but the gamma sources such as cobalt-60 can be hazardous if precautions are not taken using suitable screening.

The development of profile/flash radiography has made it possible to detect CUI on a relatively small diameter piping without the need for insulation removal using small lightweight, battery-operated flash X-ray equipment and X-ray image intensifiers with a primary conversion screen having a very short decay time, and a camera optically coupled to the output screen.

#### 4.36.2.5.4 *Magnetic techniques*

When a ferromagnetic component is magnetized, the magnetic lines of force (the magnetic flux) are mostly inside the material of the component. If, however, there is a surface-breaking flaw or crack or a subsurface flaw, the field is distorted, causing local magnetic flux leakage (MFL) fields. The flaw or crack causes a sudden local change in permeability.<sup>75</sup> The various methods of magnetization can be grouped as current flow, magnetic flow, or induced current flow where AC current from a magnetic yoke is made to flow in a specimen. This is the basis of the magnetic particle inspection (MPI) technique for detecting surface breaking defects that is described in a later section.

The induced currents produced by magnetic fields, which vary with time in conducting materials are called eddy currents. The eddy currents set up secondary magnetic fields, which oppose the original magnetic field in direction, so that the magnetic field inside the component undergoing test decreases in intensity with distance below the surface.

For inspection purposes, there are various ways to achieve magnetization such as residual magnetism, current flow techniques, or the use of a threading bar or cable. The choice of the technique is dependent on the shape and size of the specimen, the expected directions of critical flaws, and whether an overall or a local examination is to be performed.

Examples of interest to the corrosion engineer are MFL developed for ILI vehicles for the inspection of pipelines and a trolley used for inspecting the floors in above-ground storage tanks.

#### 4.36.2.5.5 *Electrical techniques*

Application of eddy current techniques involves the interaction of a coil carrying an AC current with a test piece of metal. The current passed through the coil generates circulating eddy currents in the metal test piece near the surface, which will affect the exciting current in the coil due to mutual induction. Any variation in material thickness or localized defects such as pinholes will affect the strength of the eddy currents. Coils can be single or in a double configuration used as a bridge balancing circuit. The coil can be mounted in a suitable probe, which is moved over the test sample. The system was developed originally for the inspection of defects and pinholes in nonferrous heat exchanger tubes on the assembly line following manufacture. At a later stage in the development of the technique, coils were wound on a bobbin and mounted in a suitable holders for insertion into the bores of heat exchanger tubes, allowing them to be inspected in

service when offline. Despite complications at the locations of baffle plates used for tube support, valuable data were obtained.

A system for CUI inspection uses pulsed eddy currents without the necessity for the removal of the insulation. A special coil is positioned on top of the pipe insulation. The coil incorporates a transmitter and receiver coil and a magnetic field is established in the steel wall. The receiver coil measures the time of arrival of the eddy currents at the back wall. At places with wall loss, the arrival time will be earlier than at places with no wall loss. From this time of arrival, the average wall thickness can be calculated. The system can measure wall thickness through up to 100 mm insulation, including chicken wire as well as steel and aluminum sheeting. The time of measurement is 2–5 s and up to 1000 measurements can be made daily. In addition to insulated piping, the method has been applied to vessels, elbows, tank walls, and tank roofs.

#### 4.36.2.5.6 *Dye penetrant (DPI) and magnetic particle (MPI) surface crack detection*

Penetrant testing is a low-cost technique that is widely used to detect flaws and defects that penetrate the surface. The technique can be used on any non-absorbing surface. Following surface cleaning, a liquid that wets the surface is applied and migrates into defects and cracks by capillary action. Any excess liquid is removed and then the liquid in the crack is drawn out by a suitable developing agent. The liquid incorporates either a red-dye or a fluorescent substance, in which case, observation is carried out using ultraviolet light. For field testing, the technique is applied on a manual basis. The technique is particularly effective for the detection of SCC, which shows very little visible evidence at the surface in contrast to other forms of corrosion attack that reveal themselves by surface corrosion products.

Magnetic particle testing (MPI) is a related technique for the detection of surface breaking cracks/defects in ferromagnetic materials. The specimen is magnetized, usually with portable electromagnets. Surface flaws distort magnetic fields, causing local MFL around the flaw. White matt paint is applied, following which finely divided magnetic particles are applied to the test area in air or a liquid suspension, which decorate the line of the flaw. Fluorescent particles aid visual discrimination in ultraviolet light. The technique is rapid, low cost and more tolerant of surface finish than the dye penetrant method. However, it is restricted to ferromagnetic materials.

Both the techniques are limited to surface temperatures that are less than  $\sim 60^{\circ}\text{C}$ .

#### **4.36.2.5.7 Acoustic emission**

AE has been used to detect and locate flaws in metal or FRP-pressurized systems in a wide range of applications in several industries. It was universally adopted when first introduced but controversy related to interpretation and cost resulted in user disillusion. However, confidence returned after a few years following overall improvements in both hardware sensitivity and data interpretation, although a recent view was that the technique remains closer to its infancy than to full maturity.

The technique involves raising the pressure beyond design/previous operating levels during proof or in-service inspection. This induces elastic deformations and defect micropropagation processes release stored elastic strain energy, partly in the form of propagating elastic waves (AEs). Surface-mounted piezoelectric probes detect emissions and emission amplitude is a guide to severity. Triangulation techniques position emissions within  $\sim 10\text{ mm}$ . Defects must propagate to provide a signal response. Existing defects that do not propagate will not give a response and will therefore remain undetected. The technique has gained wide acceptance for the testing of pressurized systems provided that they can be pressurized above their operating pressure and an adequate number of appropriate sensors can be applied externally. Typically, for a sphere of 16 m (53 ft) diameter,  $\sim 30\text{--}40$  sensors are required. If insulation is present, only small holes in the insulation are required. An examination can be carried out in 1 day after installation and setup.

Hardware developments have been mainly associated with improvements in electronics enabling differentiation of acoustic noise from overall background noise. However, the major advances have related to signal classification, and emissions are usually graded as a function of the number of hits and their amplitude in categories that range from very minor, to be noted for future reference, to intense, requiring immediate shutdown and follow up NDT/E methods such as surface crack detection and ultrasonic testing to locate and dimension defects, as illustrated in [Figure 22](#).

From the corrosion standpoint, the identification of cracks is of much interest and finger-prints of the cracks can be compared at prescribed intervals to see whether crack growth is occurring.<sup>78</sup> The use of AE to detect active corrosion (progressive loss of

wall thickness) in above-ground storage tanks has been reported.<sup>79</sup>

AE testing is carried out onsite by specialist companies and is not routinely available from NDT/E contractors. The level of operator training is most critical to correct interpretation of data. A Euro-funded project to develop an AE system for assessing corrosion in marine oil tankers is now in progress.<sup>80</sup>

#### **4.36.2.5.8 Thermography**

Infrared cameras are very effective for remote temperature measurements, which are extensively used in plant for checking the efficiency of insulation, boiler component temperatures, and flare tips. In some plant applications, a direct relationship has been established between temperature excursions and corrosion. The technique has been used for assessing the thickness of oxide films on the fire-side of power station boiler tubes when offline. This is somewhat tedious with the requirement for scaffolding but the method gave interesting results and provided criteria to assess the progress of corrosion.

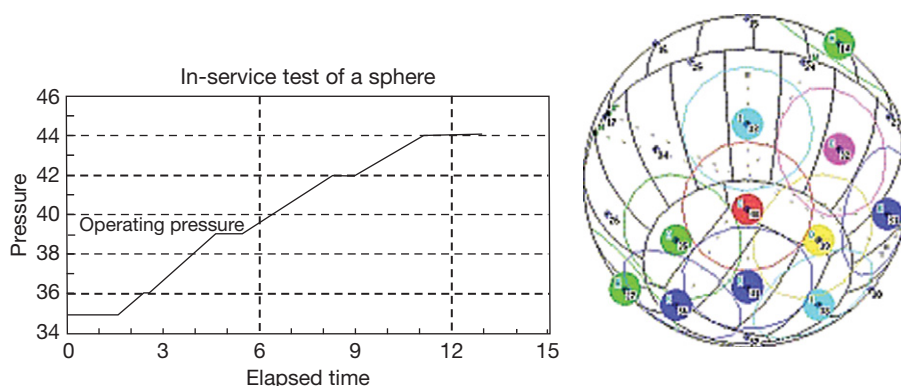

The examination of insulation to detect broken or missing insulation using infrared cameras has proved useful for the detection of CUI.

#### **4.36.2.5.9 Fiber optics**

Structural monitoring has attracted special interest in the technical press regarding the detection of failure modes in structures such as the cracking of materials. Sensors utilizing fiber optics have been tested and installed in a number of constructions, in particular bridges, for example, in Canada where bridges have had fiber optic sensors (FOS) fitted since 1998.

Sensors using FOS have been fitted to pipelines and can detect pipe movement by monitoring any change in the neutral plane of the pipe from its initial reference state and can also measure any bending strains that occur due to pipe movement. Monitoring these strains and associated stresses can provide warnings of potential pipe failures. FOS systems can measure structural displacements, strains, pressure, vibration, and temperature. Types of sensor include point sensors such as fiber Bragg gratings and Fabry–Perot sensors. Changes in wavelength that occur are proportional to the strain induced in the structure. Fabry–Perot sensors also respond to strain. Sensors referred to as distributed include Raman and Brillouin Scattering and measure a change in wavelength of scattered light.

FOS are now available for detecting the presence of wall thinning due to general corrosion or erosion

Category	AE source	Action
A	Very minor	Note for future reference
B	Minor	Inspect visually for surface defects
C		Follow up NDE
D	Significant	Immediate follow up NDE
E	Intense	Immediate shut down and follow up NDE

**Figure 22** Acoustic emission assessment based on grading emissions as a function of the number of hits and their amplitude as applied to storage sphere.

and allow monitoring of a pipe section to ensure fitness for service. The sensors are noninvasive and can be mounted on pipes and pressure vessels. Sensors are designed to precisely measure temperature, pressure, and the localized swelling of pipeline walls that signal the presence of corrosion.

Corrosion monitoring using FOS has been carried out in a Middle East gas processing plant and oil refining operations for hard-to-reach areas or remote locations. A FOS system was installed on a 12-inch (305-mm) by 20-inch (508-mm) reducer, connecting a gas feed line into a large pressurized vessel. Because of the diameter change from top to bottom, the geometry presents a difficult shape to monitor and to analyze the data. UT monitoring was carried out simultaneously and a trend of wall thickness was demonstrated with both UT and FOS.<sup>81</sup>

#### 4.36.2.6 ILI of Oil and Gas Pipelines

##### 4.36.2.6.1 Background

In 1996, a European organization, Conservation of Clean Air and Water (CONCAWE) produced figures

for oil pipeline spills in Europe for 1994, reporting that eleven incidents of spills totaling more than 15 000 bbl occurred, one of the costliest spill years on record. Cleanup operation recovered less than 2500 bbl of oil. Final costs for cleanup were reported as \$9.7 million, with two spills accounting for \$9.1 million. The actual cleanup costs for the same year would have been higher because costs for the second largest spill were not reported. Corrosion was the third highest cause of incidents with third-party damage being the largest cause.<sup>82</sup> In 2005, 6226 km or 18% of the total length of the European inventory was inspected by various types of inline inspection (ILI) vehicles. Inspections were split among the individual classes of vehicle, as follows:

1. Metal loss ILI – 5860 km in 105 sections
2. Crack detection ILI – 2132 km in 34 sections

CONCAWE has given the reason for improved performance and lower spills as increased use of ILI. The same situation prevails in the USA and many other countries. The benefits of ILI technology cannot be overestimated in its contribution to the safety of ageing pipeline systems.

In the USA, there has been much debate relating to a compulsory requirement for ILI and various Bills have been discussed by the US Congress without a final conclusion yet regarding the contentious aspect of inspection frequencies, in particular, whether the interval between ILI inspections should be 3 or 5 years or some other interval. Many US pipelines are now approaching 50 years of age and European landlines will soon approach these lifetimes with offshore pipelines somewhat younger at ~35 years. The consequence of high-pressure pipeline failure due to corrosion can be catastrophic and much effort has been devoted worldwide to the development of inspection devices for pipelines.

An early pipeline failure in the UK involved a 12-inch (305-mm) pipeline supplying the Shell Stanlow oil refinery when 150 tons of crude oil polluted a 32-km stretch of the Mersey estuary due to a pipeline fracture and killed an estimated 300 birds with a further 3000 at risk. In the first major prosecution by the National Rivers Authority (NRA), Shell pleaded guilty to spilling the oil. The court heard that a 6.5-inch (165-mm) crack in the pipe had been caused by the wrinkling of a protective sleeve. Tests found no weakness in the pipe although it had been planned to adapt it, at a cost of £100 000, to enable the use of a fault-detecting device known as an intelligent pig.<sup>83</sup>

A far more serious major pipeline event occurred in 2000 in the USA and involved a gas line carried under a bridge in Arizona. An underground pipeline, owned by the El Paso Energy Co. and installed in 1952, ruptured and discharged flammable gas, engulfing an adjacent campsite in flames and killing eleven tourists. The incident was investigated by the DOT and was shown to be due to internal corrosion. The pipeline had been inspected in 1996. The company was fined \$2.52 M by the DOT.

Many other incidents of pipeline failure have occurred in the USA such as the gasoline leakage at Bellingham, WA in the summer of 1999 when a pipeline failed due to damage from construction activity near the pipeline, which contributed to the rupture resulting in the deaths of three young people. The two companies involved, Olympic Pipeline Co. and Shell Pipeline Company LP, were likely to face fines each totaling \$18.6 m. This incident prompted the US Senate to pass the Pipeline Safety Improvement Act of 2000, aimed at increasing penalties for safety violations, increasing state oversight of pipelines within their borders, and requiring pipeline companies to publicly disclose information about pipelines on the internet.

The corrosion of pipelines can occur on both internal and external surfaces if appropriate and adequate corrosion control measures are not carried out and monitored. Although some material upgrading from carbon steel has taken place, particularly offshore, the major proportion of pipelines are still constructed from carbon steel. In addition, pipelines can be subject to SCC and although this failure mode is more difficult to monitor, there are now ILI versions available for the detection of cracks.

External inspection using ultrasonic wall thickness will not give a comprehensive picture of the degradation (if any) at inaccessible locations of the pipelines as both onshore and subsea pipelines have an uneven elevation and debris and water can collect at discrete points within the pipelines and cause corrosion to be initiated. John *et al.*<sup>84</sup> point out that corrosion monitoring data will only provide an assessment at the actual location where the probes or coupons are located.

To overcome some of the above problems, an approach to modeling the metal loss within pipelines has been attempted by combining an assessment of the historic operating parameters over the life of the pipeline and calculating a cumulative metal loss since commissioning, while also allowing for the unknown variations in operating parameters by the incorporation of uncertainty analysis. Two case histories have been reported using this approach on a subsea line in the Middle East and a pipeline in the North Sea.<sup>84</sup>

#### 4.36.2.6.2 Development of ILI vehicles

An ILI vehicle for the inspection of pipelines is referred to in the oil and gas industry as a pipeline inspections gauge (PIG), a device incorporating onboard instrumentation that is propelled under pressure from the product being transported through pipelines and which collects and records inspection data relating to both internal and external corrosion.

From the beginning of the oil industry, pipeline operators have utilized devices that are passed through the pipelines for cleaning the interior and removing paraffin waxes and sludge. Later, devices incorporating mechanical feelers that were used to detect mechanical damage such as dents or ovality were introduced. Vehicles containing various NDT/E sensing equipment using magnetic saturation arrived in the mid-sixties. However, pipeline operators became disillusioned with these devices due to the number of false positive signals. Excavation to verify suspect areas often revealed little corrosion, if any, and initial interest shown by pipeline operators and

oil companies soon diminished. In addition, the classification of the corrosion information was very qualitative in nature. For one model, the corrosion indication was only classified into three categories designated as low, medium, and severe corrosion.

An up-rated ILI was developed on behalf of British Gas (BG) in the late eighties using MFL. Prior to the introduction of the improved device, BG tested their high-pressure lines hydraulically, which required the line to be taken out of service. This was the first time that an ILI was available that could be judged in performance terms on a quantitative measurement of corrosion. The early development gave a defined specification for sensitivity, as shown in Table 7.

The BG vehicle design provided a benchmark for the industry and high-resolution versions based on magnetic flux and ultrasonics were subsequently developed in Canada, Germany, and Japan. The development of these vehicles was a major advance in pipeline inspection made possible by improved computer power and developments in electronics. The detection of cracking has been a long-held objective of pipeline operators and versions are now available for this purpose using EMAT systems.

Intelligent vehicles are inserted and removed from pipelines through pig-traps. Essentially, the vehicle comprises two or more sections, one section contains the sensing equipment, the sensors and other sections contain the electronics and batteries. The rear section contains the odometer wheels to measure the speed and distance of the vehicle. The improved ILI vehicles could not be used at first, because they were too large for the existing pig traps. This was the case for offshore platforms initially, where space is always at a premium. However, later designs of platforms and pipelines took account of the additional size and appropriate pig-traps were installed.

Not all pipelines can be inspected by ILI vehicles for reasons that include economics (costs of

inspection), varying pipeline diameters and geometry (angles, sharp bends), or other constraints inside lines. It is generally considered that the minimum size of line is 152 mm (6 inch) but special caliper devices may allow the inspection of lines down to 76 mm (3 inch) diameter.

Intelligent vehicles use several techniques for their operating mode. MFL continues to be the most common for inspection of pipelines.<sup>85</sup> Accuracy for these vehicles is estimated at  $\pm 10\%$  at the 80% confidence factor. Ultrasonic vehicles were developed because MFL vehicles were not accurate enough to allow calculation of the remaining strength. The ultrasonic vehicles are better able to measure the wall thickness and the results can be used directly in calculations (e.g., RSTRENG) to determine the remaining strength. Note that ultrasonic methods require a liquid in the line for operation (unless they are in a liquid slug) for the transmission of the ultrasound. Each technique has advantages and disadvantages and the usual strategy adopted by pipeline operators is to alternate inspections between the different systems.

Vehicles using elastic waves have been produced for crack detection with liquid-filled wheels for the transmission of the waves into the line but it is reported that too many false positives are produced. Vehicles using EMAT systems have also been developed for SCC obviating the need for a transmission medium.

#### 4.36.2.7 Management of Inspection Programs

Many organizations undertake visual inspection and metal thickness measurement in-house. Inspection functions are generally well managed and have clearly defined roles in the company structure. Communication is a vital component of success and is more difficult for oil and gas operations compared with land-based, permanent sites. Coordination and liaison are most important regarding process information, corrosion data, and inspection schedules as well as everyday factors relating to overall operations. A UK HSE investigation into the inspection functions in oil refineries suggested that inspectors should be embedded in units in order to improve liaison. The introduction of RBI (risk-based inspection) has improved overall cooperation; however, it still requires continuous monitoring on a quarterly basis to avoid problem areas. The updating of records as well as management of contractors should have high priority. The regular issuing of the minutes of meetings should also be given priority. Resistance to changes in previous practices can be avoided by fully describing

**Table 7** British gas ILI vehicle-magnetic flux leakage (MFL) – specification for corrosion detection (Data supplied by British Gas)

	Detection sensitivity	Sizing accuracy
General corrosion	0.2t	+ or – 0.1t
Pitting corrosion	0.4t	+ or – 0.1t

Where  $t$  = nominal pipe wall thickness (seam welded pipe) and pitting corrosion defined as corrosion affecting a surface area of pipe contained within a square of dimensions  $3t \times 3t$ .

reasons for the changes and providing evidence that there needs to be such changes.

Specialized contractors make a large contribution in the inspection sphere but they have to be supervised and managed effectively. In some cases, the total inspection function will be contracted out (as is the case for most offshore oil/gas production) with the contracting workforce embedded at the plant premises and producing daily and monthly reports for the plant management. An important factor is the training received by the contractor's technicians as well as reliable record keeping and overall technical ability. Continuous training is required and on-the-job training is not sufficient. Operatives and supervisors need to be qualified and supervised on an ongoing basis. The selection of contractors requires careful consideration, including, of course financial stability. The author has had good experience working with NDT/E over many years with contractors chosen by personal recommendation wherever possible.

The cost of inspection is similar to any other high-tech service for high capital cost equipment and relates to the complexity of the equipment used and the degree of training required for its operation and interpretation. Reference has already been made relating to the qualifications of personnel involved and how the ASNT (US) and BINDT (UK) have been instrumental in raising the level of qualification and assessment of examinations. Costs have steadily increased due to the resulting improved qualifications of NDT/E personnel, which most of industry has welcomed.

The existence of international, national, and company standards coupled with legislation relating to maintenance and inspection of industrial infrastructure is of considerable assistance, but presents a challenge to those engaged in the inspection process. Accordingly, systems and procedures require regular appraisal and revision. There are many sources of standards and codes of practice. In addition to the main societies relating to NDT in both the USA and Europe, many countries have their own standards to which reference should be made first, followed by those produced by relevant engineering and scientific bodies. The standards of the European Economic Community are issued as ISO documents. The Russian Federation has a considerable expertise and reputation in this technology, and despite an emphasis on the academic interest, some of this experience has trickled down into the industrial sphere. Some of these standards are very specific to certain materials and environments. Some organizations of particular relevance are:

1. International Standards Organization (ISO).
2. American Petroleum Institute (API) has responsibility for the infrastructure used for the extraction of oil and gas, storage, transportation, and downstream infrastructure in refining crude oil. The use of pipelines for both subsea and onshore is also considered.
3. American Society of Mechanical Engineers (ASME) issues recommendations relating to inspection, especially relating to boilers.
4. ASTM is mainly, but not exclusively, oriented to laboratory R & D.
5. Institute of Petroleum (IP) based in London has a number of technical committees that issue both guidance and recommendations for general practice in the industry.
6. British Standards – reference should be made to BS: EN 10204:2004 Metallic Materials. Types of Inspection.

Nonmetallic materials such as plastic/polymer and FRP materials can be inspected using some of the methods described in this chapter. Standards exist for some of these materials.

Close liaison between the inspection and safety functions within organizations is essential. Most inspection equipment requires electrical power, and therefore, compliance with intrinsic safety legislation, and there is no reason why any instrumented system cannot be engineered to meet the requirements. The usual plant safety rules regarding access to heights and entry to confined spaces must be complied with. The use of ionizing radiation requires precautions, particularly relating to shielding.

It is particularly important that precautions are taken to check that dangerous gases have been purged from equipment and that vessels are tested for the presence of sufficient oxygen. Fatalities have resulted from entry into vessels where the oxygen level was insufficient to support life. For example, a cruise-ship crew member died recently from suffocation during an inspection of tanks for corrosion, prior to departure from Southampton in the UK and another crew member had to be rescued from the tank.<sup>86</sup>

#### 4.36.2.8 Specific Industries

##### 4.36.2.8.1 Oil and gas industry equipment

Inspection functions are usually influential in oil and gas companies because plants have to operate for long periods between scheduled shutdowns and

there is a strong interest in onstream inspection. Communications are more difficult in production compared with refining due to the remoteness of production fields, both onshore and offshore. The introduction of RBI has focused the inspection process to a great extent than in earlier days when the approach was more random.

The most common inspection technique is observation utilizing the human eye and measuring equipment of various kinds such as calipers and gauges. These techniques are supplemented by cameras and TV and sometimes with borescopes and similar equipment, albeit such techniques are generally restricted to shutdown periods with corresponding drawbacks.

Downhole inspection presents particular problems due not only to the high temperatures and pressures but also to limited access. A widely adopted inspection system for downhole corrosion involves the Kinley mechanical caliper (involving a number of feelers), which, apart from resolution problems (inadequate coverage of the 360 degree tubing circumference), is still widely used in the industry. A major problem involves mechanical damage to the oil-tubing surface, which can damage any inhibitor films that are present. This is overcome to some degree by increasing the dosage rate of the inhibitor for a short period when production resumes. Downhole cameras and television are available for visual examination as well as various types of electrical instrumentation. Increasing use of CRAs downhole will reduce the requirement and/or frequency of such inspections, although acid treating of wells to remove scale and formation damage will still need verification that damage to the metal has not occurred.

Ultrasonics, usually undertaken by contractors, is commonly used for thickness measurement and for detecting cracks in pipelines and vessels. Welded probes and phased array probe system, which can provide a continuous signal are also used in critical situations and can mitigate the need for operators to visit remote and/or dangerous locations. Above-ground storage tank walls and roofs can be inspected online, using automatic crawlers held to the steel surfaces by magnetic attraction.<sup>87</sup> Infrared cameras are useful for surveying hot-spots in equipment and for locating insulation failures. There have been many examples where a correlation has been made between increased corrosion and an increase in temperature. AE by specialist contractors at intervals is used for the assessment of both the onset of cracking and crack growth.

#### **4.36.2.8.2 Chemical and petrochemical plants**

As in the oil and gas industry, plants are operated for long period between scheduled shutdowns, and hence, the approach to inspection is very similar. The shutdown period is utilized for much visual and hands-on inspection to verify that materials behavior complies with expectations from online inspection. Plants utilize extensive amounts of CRAs that increase the focus on localized corrosion failure modes such as cracking and pitting corrosion. The plants commonly use waste heat to raise steam and require extensive water cooling systems, which introduce additional inspection requirements.

#### **4.36.2.8.3 Power plants**

Unscheduled outages in these high capital cost facilities can be very costly as power has to be bought from other suppliers at high cost and some material upgrading, for example, the introduction of titanium condenser tubes, has occurred over the years to reduce corrosion risks.

Fossil fuel and gas-fired stations are subject to corrosion in boiler tubes (water and fire-side) and water circuits, which have to be inspected using most of the available NDT/E techniques. The inspection challenge is greater in nuclear stations. The first series of UK advanced gas cooled (AGR) nuclear reactors (Magnox) have a relatively poor record regarding corrosion. Excessive corrosion of some carbon steel fasteners in the gas cooling conduits was experienced, which required an operating temperature reduction and consequent loss of efficiency.<sup>88</sup> A later design (Dungeness AGR) also experienced corrosion problems with carbon steel linkages and where zinc-coated wires embrittled stainless steel tubes necessitating a downrating. More recently, some of the nuclear power stations (Hartlepool and Heysham 1) have had to be shutdown due to corrosion problems in wiring corrosion in steel and concrete boiler units attached to the reactors. It is believed that up to \$10 M will be required to investigate corrosion in the 54 km of wire involved in the units.<sup>89</sup> The root cause is believed to lie in the original design and construction. In total, eight reactors are experiencing corrosion and cracking related to ageing and these problems have presented considerable inspection challenges. In addition to the conventional range of NDT/E techniques, special systems have been designed solely for the nuclear industry.

An interesting NDT/E device designed for the inspection of high-voltage transmission lines for corrosion (loss of zinc coating on the steel core) involves

**Figure 23** High voltage cable corrosion detector (Courtesy Cormon Ltd).

the use of eddy currents. The lines can be inspected when carrying current using a trolley-carriage that traverses the lines, as shown in [Figure 23](#).

The device was developed in the UK and has been widely used in the UK, France, Ireland, and Sweden.

#### 4.36.2.8.4 Defense

Many corrosion problems are experienced in defense infrastructure and systems. Individual countries have their own specifications and standards. Corrosion is particularly severe in naval operations and corrosion protection and inspection are well organized and implemented but problems still occur from time to time. Accordingly, most of the NDT/E techniques are implemented. Military aircraft are appreciably ageing compared with civil aircraft and present a severe challenge to the inspection function. One historical aspect relating to fuselage inspection relates to the use of primer (where fuselage panels are riveted together), which can mask the penetration of X-rays – now largely replaced with techniques using eddy currents.

Military missiles now have casings made from carbon fiber, Kevlar, or other materials wound in layers, which results in weight savings of up to 40% compared with metals. Their light weight also makes them less expensive to ship and easier to handle. However, the missiles are sometimes damaged when struck by rock and debris kicked up by helicopter rotors or when mishandled during shipping or maintenance. Unlike metals, which usually show external signs of damage (such as cracks or dents), the filament-wound composite materials may not reveal telltale signs. A new monitoring system developed in the USA (Purdue University) uses a mathematical model to pinpoint the location and severity of impacts based on vibration data collected by a triaxial

accelerometer. The objective of the project is to have a permanently installed system to monitor the structural health of the missile. The information obtained enables the monitoring system to determine within seconds whether an impact is beyond the design threshold. The technique also would determine how durable the material is after long-term storage and exposure to humidity, UV radiation, and other environmental conditions. Materials under examination include sandwich metallic materials, woven composites, ceramics, and filament-wound materials. Components of particular interest are wheels and spindles.

#### 4.36.2.8.5 Marine

The progressive use of higher strength steels for shipbuilding has resulted in significant weight savings by reducing thickness but has inevitably exacerbated corrosion risks. Accordingly, inspection has become more critical than in previous years.

Major ocean-going vessels require a fit-for-purpose certification at prescribed intervals in order to operate. This process involves much inspection mainly in the area of coating inspection. However, not only has the vessel integrity to be established, usually in dry dock, but also the onboard facilities such as boilers and fire, cooling, potable, and discharge water systems among others. Vessels change cargoes at short notice and tanks require complete cleaning between each change of cargo. Other marine infrastructure such as dock facilities, jetties, cranes, and oil-loading facilities also require inspection.

#### 4.36.2.8.6 Road transportation

Transportation includes road vehicles (private and industrial), rail transport (wheel and track inspection being the main priority), and aircraft. Road vehicles can suffer from body corrosion, now mostly designed out. Trucks can suffer from various corrosion problems, especially road tankers used for potentially aggressive liquid cargoes that require periodic internal inspection. Regular inspection of pipes carrying hydraulic brake fluid is necessary as corrosion degradation is not unknown and incidents have caused loss of life.

#### 4.36.2.9 Future Developments

The resolutions and response times of some inspection and corrosion monitoring techniques are shown in [Table 8](#). These define the state-of-art and the current challenge for the future development of inspection technologies.

**Table 8** Resolution and response time for some corrosion monitoring and inspection techniques

<i>Technique</i>	<i>Resolution</i>	<i>Response time at 1 mpy (1/40 mm year<sup>-1</sup>) corrosion rate</i>	<i>Response time at 40 mpy (1 mm year<sup>-1</sup>) corrosion rate</i>
Electrochemical	1 $\mu$ A	minutes	minutes
FSM™ 25 mm wall thickness	0.025 mm	1 year	days
Electrical resistance	0.00025 mm	4 days	minutes
Ultrasonic thickness transducer (fixed)	0.1 mm	4 years	40 days
Weight loss coupon	1 mg	months	days

Source: Joosten, M. W.; Fischer, K. P.; Strommen, R.; Lunden, K. C. *Mater. Perf.* **1995**, 34(4), 44–48.

General improvements in data capture and handling combined with developments in electronics, in particular relating to miniaturization, should bring exciting developments and improvements in inspection technology. This will apply to most of the existing techniques for inspection such as ultrasonics, eddy current, and AE. The detection and monitoring of cracks is of much interest and will receive particular attention in the future. Some specific likely developments are as follows:

1. Miniaturization is of much interest regarding the internal inspection of process piping with hopefully the sensitivity approaching that of intelligent vehicles presently used for buried and offshore pipelines. There are still problems to be solved, with the sharp bends and the many obstructions present in a process plant piping, but this is the most interesting area of activity.
2. Development of the EMAT systems and better performing portable ultrasonic array systems will receive attention.
3. Interest has been expressed in fiber optic strain sensors used for civil engineering structures that could be adapted for use in process plant for corrosion detection and measurement.<sup>90</sup> As corrosion or other chemical reactions occur, the transverse strain is relieved and the peak-to-peak spectral separation changes allow a measurement of corrosion. Different metals and stretchable plastics can be used as a component to support the measurement of a variety of corrosion events.
4. A research program organized by the Southern Illinois University Carbondale Material Technology Center is in progress to develop an internet-based wireless sensor network that will provide real-time data and analysis on the structural soundness of transportation infrastructure, such as bridges.<sup>91</sup> The three-year project, initiated in October 2007, is funded by a \$1 M grant from the US Federal Highway Administration (FHWA) Intelligent Transportation System's program. The concept involves placing several types of sensors on

a structure to detect variable such as stresses, elongation, deformation, vibration, cracking, and corrosion. Sensor technology includes existing sensors such as strain gauges, accelerometers, and pH sensors as well as new sensor technology developed in conjunction with the project.

5. It is possible that other data sets may be added to ILI vehicles in the future, which should assist the operator's ability to proactively detect possible corrosion threats to pipeline integrity other than metal loss.<sup>92</sup>
6. In 2007, a new Research Center in Nondestructive Testing was established in the UK with initial funding of \$3 M over 5 years. Participating universities are Imperial College, Strathclyde, Bristol, Bath, Nottingham, and Warwick. It functions as an industrial club and carries out research projects of interest to club members.

### 4.38.1 Airframe Corrosion

#### 4.38.1.1 Introduction

This chapter is concerned with the management of corrosion on fixed wing aircraft and helicopters. It concentrates on the corrosion and protection of aircraft structures and does not consider the complex corrosion problems associated with the protection of materials used in aircraft engines. Although the references and discussion are mainly concerned with aircraft, the approaches described are also applicable to other aerospace structures such as guided weapon systems and airships.

The principal materials used in the construction of the modern aircraft are aluminum alloys, titanium alloys, high-strength steels, corrosion resisting steels, magnesium alloys, and composite materials.

Weight has always been the main consideration in airframe construction. The structure must be light, but strong enough and rigid enough to withstand the applied loads and stresses. The specific strength and resistance to buckling are important factors in the selection of airframe materials. For these reasons, extensive use of aluminum alloys has traditionally

been made in the aerospace industry. With the development of composite materials, such as carbon fiber reinforced plastics, the volume of aluminum alloys employed on the modern civil transport aircraft and military fast jet has been significantly reduced. As will be discussed later in this chapter, this will have an impact on aircraft corrosion and protection.

High-strength steels are used in a number of applications. In areas where size is critical, steels have advantages over aluminum alloys. Landing gear components, for example, have to be stowed away into relatively small volumes. To achieve the necessary load carrying capacity, parts are frequently manufactured from steels having tensile strengths in excess of 1800 MPa. Many fasteners used on aircraft are also manufactured from steel.

Strength is not always the overriding criteria. Some applications require a high level of stiffness and this can be obtained through the use of thick section. Gearbox housings are one example in which it is more advantageous to use a magnesium alloy casting. The same part manufactured in an aluminum alloy would be 1.5 times heavier. Titanium alloys are also finding increasing applications in airframe components and are replacing steels in some areas. Titanium alloy fasteners are also extensively used on modern aircraft.

Corrosion can have a major impact on the structural integrity and hence safety of all types of aircraft. To implement a successful corrosion management program, an understanding of the operating environment and the potential corrosion risks associated with the various materials used in the airframe structure is essential.

Neglecting to manage corrosion may lead to the eventual grounding of an aircraft because it is structurally unsound and unsafe to fly. A planned approach to the management of corrosion on aircraft is therefore necessary to ensure safety and reliability and begins at the design stage of the aircraft.

#### 4.38.1.2 The Operational Environment

Aircrafts are frequently operated in highly corrosive environments. For example, many military aircrafts fly from coastal bases and carryout low level missions over the sea. Aluminum alloys, high-strength steels, and magnesium alloys are highly susceptible to various forms of corrosion in the presence of chloride ions if they are not adequately protected.

The AGARD Aircraft Corrosion Handbook<sup>1</sup> has summarized the relative rates of corrosion for different types of atmosphere. It lists tropical, industrial,

and marine environments as highly conducive to corrosion, while rural and arctic locations are considered to give a low rate of corrosion. Moderate corrosion occurs when flying is in temperate or suburban regions. Some desert areas have high levels of salt and are potentially highly corrosive.

In addition to contaminants from the environment, there are a number of compounds and liquids that are used on the aircraft, such as hydraulic fluids, fuels, and oils, which can degrade protective treatments and may lead to the onset of corrosion. In addition, spillages from galleys, toilets, and batteries and breakages in freight-holds have all been identified as initiating corrosion. These areas need particular consideration in terms of design and protection to minimize the risk of corrosion in-service. Condensates from passengers and livestock will also promote corrosion. Mitchell<sup>2</sup> has described a UK airline's experiences with many of these contaminants. Reference is made to the soundproofing adjacent to the fuselage, which was found to absorb up to 400 kg of moisture, presenting a major corrosion threat.

During maintenance, a range of chemicals is used for washing, cleaning, and removing paint from the exterior and interior surfaces of the aircraft. These materials if not used correctly and in the right concentrations may lead to corrosion, particularly if allowed to enter the internal structure of the aircraft. Specifications covering cleaners, etc., for use on aircraft include corrosion tests designed to ensure that potentially corrosive materials are excluded. Similarly deicing materials used on aircraft and for clearing runways must satisfy these corrosion tests.

Early studies conducted by Kohler and Scott<sup>3</sup> demonstrated that significant levels of chloride ions and other corrodents can accumulate in the internal structure of military aircraft operated in a maritime role. The levels were sufficient to initiate pitting corrosion and other forms of localized attack on aerospace aluminum alloys. Future aircraft corrosion control plans will need to take into account the likelihood of corrosion developing in internal parts of the structure, which cannot be inspected by conventional methods.

Although corrosion will occur primarily when an aircraft is sitting on the ground, flying at 30 000 ft will contribute to degradation of the protective treatments used on the external surfaces. At these altitudes, the external temperatures fall to  $-60^{\circ}\text{C}$  reducing the paint flexibility. This can lead to paint cracking around fasteners, permitting the ingress of moisture. Further, the ozone and ultraviolet levels are high, causing degradation of the exterior paint

schemes. The temperature cycling experienced by the aircraft, especially when operating in hot humid environments, will lead to a continuous buildup of moisture in internal regions.

The protective treatments applied must be capable of preventing corrosion on aircraft structures when exposed to the various operating environments and contaminants listed earlier.

#### 4.38.1.3 Summary of Main Corrosion Types

The airframe materials employed exhibit a number of different types of corrosion. A key part of the management of aircraft corrosion is the knowledge of the conditions under which a specific form may develop, and the steps that should be taken to prevent or control it. Table 1 summarizes the various forms of corrosion that have been found. They may be divided into three groups as follows:

- corrosion occurring in the absence of an applied stress,
- corrosion occurring in the presence on an applied stress,
- corrosion resulting from poor design and protection.

Detailed information about the mechanisms of the different types of corrosion identified may be found elsewhere in this book. Sections 4.38.1.3.1, 4.38.1.3.2, and 4.38.1.3.3 summarize the main aspects of each form of corrosion as they relate to airframe materials.

##### 4.38.1.3.1 Corrosion occurring in the absence of an applied stress

General corrosion is included in Table 1 for completion, but in practice relatively few examples of general corrosion are found on airframe materials. More usually the type of attack that develops can be described as localized corrosion. This may take the form of pitting, intergranular, or exfoliation corrosion. In the case of aluminum alloys, the surface is protected by a thin adherent oxide film. One hypothesis is that flaws preexist in the oxide film and provide sites for the initiation of corrosion attack. The flaws may be associated with precipitates, impurities, or grain boundaries in the matrix. The dissolution of aluminum is localized and leads to the formation of corrosion pits particularly if chloride ions are present.

Pitting is often a precursor to further localized attack. In intergranular corrosion, the grain boundary areas behave anodically with respect to the bulk of the grains. The corrosion follows paths along the grain boundaries of the material and can proceed at a high

**Table 1** Summary of corrosion types found on aerospace materials

<i>Type</i>		<i>Description</i>	<i>Susceptible materials</i>
Absence of applied stress	General	Corrosion uniformly distributed over exposed surface	
	Pitting	Localized attack, which leads in the formation of deep and narrow cavities	Aluminum alloys Magnesium alloys
	Intergranular	Corrosion attack propagating along the grain boundaries of the material	Aluminum alloys
	Exfoliation	A form of intergranular corrosion occurring in materials with elongated grain structures. Leads to blistering and surface lifting and flaking	Aluminum alloys
	Microbial corrosion	Corrosion developed as a result of microbiological growth	Aluminum alloys in contact with fuel
Presence of applied stress	Stress corrosion cracking	Cracking process involving the conjoint action of a stress and a corrodent	Aluminum alloys High-strength steels Titanium alloys
	Corrosion fatigue	Accelerated fatigue growth on exposure to a corrosive environment	Aluminum alloys
	Hydrogen embrittlement	Cracking of statically loaded components resulting from the absorption of hydrogen	High-strength steels
	Fretting corrosion	Form of wear resulting from movement or vibration between two surfaces	Titanium alloys
	Solid/liquid metal embrittlement	Cracking of statically loaded components resulting from direct contact with liquid or solid metals	Aluminum alloys High-strength steels Titanium alloys
	Crevice corrosion	Corrosion resulting from the ingress of moisture into crevices or gaps between components	Aluminum alloys Corrosion resisting steels
Corrosion arising from poor design and protection	Galvanic corrosion	Corrosion resulting from the contact between two metals of different electrochemical potential immersed in an electrolyte	Direct contacts between aluminum alloys, steels, magnesium alloys in contact with titanium and CFRP materials
	Filiform corrosion	Thread-like corrosion developing under organic coatings	Painted aluminum

rate because of the large difference in cathode to anode area. If the grains are elongated in shape as in the case of plate and extruded materials, the corrosion may run parallel to the surface causing flaking and blistering. This type of attack is known as exfoliation corrosion and many examples of it have been found in-service. Often, the first indication that there is a problem arises when it is noticed that the paint film adjacent to fastener holes is lifting. At this stage, the attack may be well established and extensive repair work may be required.

In addition to aluminum alloys, magnesium alloys and steels may exhibit pitting corrosion when exposed in an aircraft environment.

Microbial corrosion is a type of attack initiated by the presence of organisms such as fungi and sulfur-reducing bacteria. Examples of this form of corrosion have been found in fuel tanks. Bowden<sup>4</sup> describes the action of *Cladosporium resinae*, a fungus which may live in water droplets present in fuel tanks. The acidic by-products produced by the fungus may breakdown

the protective treatments applied to the interior of fuel tanks and lead to the attack of the aluminum alloy substrate. Sludge developed as a result of the microbial action may lead to blockage of fuel pipes and pumps.

#### **4.38.1.3.2 Corrosion occurring in the presence of an applied stress**

Stress corrosion cracking (SCC) and corrosion fatigue result from the synergistic action of an applied stress and a corrosive environment. In the case of SCC, a static tensile stress is present, while in corrosion fatigue the stress is fluctuating in some manner. Stress corrosion failures have occurred in-service mainly with the high-strength aluminum–zinc–magnesium alloys such as 7075 and examples of failures have been seen on landing gear components. The stresses responsible for cracking are generally either residual stresses introduced as a result of the material manufacturing process or stresses arising from poor alignment during assembly. Once initiated,

the stress corrosion crack can propagate rapidly and catastrophic failure may eventually occur.

The mechanism or mechanisms of SCC in aluminum alloys continue to be the subject of much research and discussion and are covered in some depth elsewhere in this book.

In addition to high-strength aluminum alloys, high-strength steels and titanium alloys may also suffer SCC. Steels with an ultimate tensile strength greater than 1450 MPa are generally considered to be susceptible to SCC in aqueous environments. Failures have occurred with titanium alloys when exposed to specific environments.

Fatigue is familiar to all aircraft designers and operators. The presence of a corrosive environment can accelerate the process by shortening the initiation stage and/or by increasing the growth rate of fatigue cracks. Most of the concerns and research into corrosion fatigue on airframe materials have been with aluminum alloys. The need to understand this type of corrosion has gained particular importance in relation to ageing aircraft. It is now recognized that the interaction between fatigue and corrosion is crucial in determining the integrity of aircraft structures.

On airframes, hydrogen embrittlement is normally associated with high-strength steels. Cracking takes place in statically loaded components, resulting from the absorption of hydrogen, which may be introduced as a result of corrosion occurring on the surface or from hydrogen introduced during surface finishing treatments. Rapid crack growth takes place, leading to the eventual catastrophic failure of the component. It is widely accepted that the mechanism of SCC in high-strength steels is one of hydrogen embrittlement.

The fourth type of corrosion occurring in the presence of an applied stress (identified in [Table 1](#)) is fretting, which is a form of wear resulting from the movement or vibration between two surfaces. The movement is very small, often leading to the formation of fine particles or debris. Titanium alloys are particularly sensitive to this type of degradation.

#### **4.38.1.3.3 Corrosion arising from poor design and protection**

Crevice corrosion arises in-service, largely as a consequence of poor design. Crevices provide an area in the structure where water, hydraulic fluids, and other contaminants may become trapped. The diffusion of oxygen into the crevice is restricted so that the second cathodic reaction involving the reduction of water to form hydrogen ions is favored. This increases the acidity of the solution at the tip of the crevice and will lead to accelerated corrosion of structural materials such as

aluminum alloys, magnesium alloys, and corrosion-resistant steels. The proper use of sealants and jointing compounds, to fill crevices and prevent the entry of fluids, can eliminate this type of corrosion.

Galvanic corrosion can occur when two dissimilar metals are joined. Some indication of the likely risk of coupling two different metals together can be gained by comparing their corrosion potentials. If there is a large difference in potential between the two metals, for example, 2014-T6 aluminum–copper alloy and steel, the corrosion of the more negative material, in this case the aluminum alloy, will be accelerated, while the corrosion of the steel will be reduced. The occurrence of this type of corrosion in an aircraft can be limited if coatings such as electroplated cadmium are applied to steel parts. The corrosion potential of cadmium is similar to 2014-T6 aluminum–copper alloy and therefore the driving force for corrosion is much lower.

Filiform corrosion is a form of attack that develops under organic coatings applied mainly to aluminum alloys. It appears as long filaments that spread from areas of surface damage such as cracks or chips in the coating. The development of this form of corrosion is dependant on the surface cleaning and treatments applied to the substrate.

#### **4.38.1.4 In-Service Corrosion**

Corrosion is likely to take place within the aircraft structure at areas where moisture and other corrosive contaminants become trapped. The main problem areas have been documented in the open literature<sup>1,2,5</sup> and are summarized as follows.

- Areas where fluids may collect
- Areas partly exposed to the environment
- Areas into which fluids may leak

Examples of corrosion found in-service on civil transport aircraft associated with the build up of fluids include areas below toilets, galleys, and cargo-holds. The corrosion of seat tracks arising from the spillage of drinks continues to be a major problem area. Some areas such as undercarriage bays, freight doors, access doors, and flap shrouds are regularly exposed to the environment. Leakages from hydraulic systems and batteries can rapidly degrade protective treatments.

#### **4.38.1.5 Impact of Corrosion on Structural Integrity**

Corrosion can degrade the integrity of the aircraft structure in a number of ways as listed in [Table 2](#).

Exfoliation corrosion, which is often found to develop in components manufactured from plate

**Table 2** Examples of the effects of corrosion on the integrity of airframe structures

<i>Corrosion type</i>	<i>Impact on structural integrity</i>
Intergranular and exfoliation corrosion and most forms of corrosion	Reduction in section leading to loss in strength/load bearing capacity, ductility, stiffness, etc.
Corrosion pitting	Failure of hydraulic pipes, fuel lines – leakage of fluids into areas causing breakdown of protective treatments and further corrosion
Corrosion pitting and fretting	Introduction of stress raisers leading to reduced fatigue life
Crevice corrosion	Generation of stresses at joints resulting from corrosion product wedging – breakdown of bonded joints
Galvanic or dissimilar metal corrosion	Accelerated corrosion attack of aluminum and steel components
SCC and hydrogen embrittlement	Catastrophic failure of stressed components
Microbial corrosion	Leakage from fuel tanks, blockages

aluminum alloys, can lead to a major loss in section, and hence, load bearing capacity. Pitting corrosion and intergranular attack may accelerate the initiation of fatigue cracking. The areas where attack occurs act as stress raisers and greatly reduce the fatigue life of the structure. In hydraulic and fuel pipes pitting attack can cause perforation and eventual fluid loss.

Some of the aluminum alloys employed in older aircraft are susceptible to SCC. This form of attack can develop if the component is under stress and is exposed to a corrosive environment. The stresses may be residual stresses introduced during the manufacture of the part or they arise as a result of misalignment during assembly. Once initiated, SCC may develop very quickly resulting in the catastrophic failure of the part or structure.

In some instances, corrosion may contribute to the degradation and eventual failure of adhesively bonded joints. At present, much research is being directed towards understanding the mechanisms involved in the failure within adhesively bonded lap joints on ageing aircraft and developing methods for the early detection of breakdown.

## **4.38.2 Corrosion Management During Manufacture**

### **4.38.2.1 Introduction**

The approach adopted in the management of corrosion during the initial manufacturing stage is based on the following:

- the selection of materials with inherent resistance to corrosion,
- the application of protective treatments to individual parts and components,
- careful design and assembly to minimize potential problems such as crevice and galvanic corrosion,

- the application of additional protective treatments in high corrosion risk areas.

Each of these aspects is considered in this section.

### **4.38.2.2 Materials Selection**

#### **4.38.2.2.1 Introduction**

In many cases airframe materials were initially selected to provide specific strength levels, fatigue resistance, fracture toughness properties, etc. Corrosion resistance was often only a secondary consideration. The philosophy adopted was basically to assume that the inherent poor corrosion resistance of the material could be compensated for by the application of a protective coating, typically an inhibited primer or metal coating. This assumed that the coating would remain intact and undamaged throughout the life of the component. The reality is that coatings in the form of both paints and metal deposits suffer from cracking and degradation during the operational life of an aircraft. Examples of undercarriage components manufactured from 7000 series aluminum–zinc–magnesium alloys heat treated to the high-strength T6 temper that suffered catastrophic failure in-service have been referred to earlier. In these instances the surface treatments applied failed to prevent the onset of SCC.

The approach now adopted is to take into account the inherent corrosion resistance of the material to be employed. Guidance data are available from several sources<sup>6,7</sup> on the susceptibility of airframe to various types of corrosion, in particular, resistance to SCC and exfoliation corrosion.

#### **4.38.2.2.2 Aluminum alloys**

As indicated in [Section 4.38.1.3](#) airframe aluminum alloys are susceptible to various forms of corrosion including localized attack and SCC. The alloy

composition, heat treatment, and product form will control the type and distribution of precipitates as well as the grain size and shape of the grains. The microstructure of the component material, together with the nature of the environment and loading applied, will determine the type and extent of the corrosion attack that takes place. During the material selection process, the resistance of aluminum alloys to exfoliation corrosion and SCC is taken into account. Extensive laboratory testing combined with service experience has enabled the relative susceptibilities of aerospace aluminum alloys to exfoliation to be given a rating as indicated in [Table 3](#) based largely on Defence Standard 00-970.<sup>6</sup>

Sheet aluminum alloys are generally considered to be immune to exfoliation corrosion and have an 'A' rating. Some intergranular attack may take place but the grain structure is normally equiaxed and true exfoliation corrosion will not develop. Alloys with C ratings should be avoided wherever possible. As discussed in the following section, surface treatments must be applied to minimize the risk of corrosion occurring. Several alloys such as plate 2024-T3 aluminum–copper, which has frequently been used for bottom wing

skin applications, and plate 7075-T651 aluminum–magnesium–zinc which has been used for the manufacture of upper wing skins and undercarriage components are very susceptible to exfoliation corrosion and have a 'D' rating. The policy now is to avoid the selection of these materials wherever possible.

[Table 4](#) compares the susceptibility of several materials that have been widely employed in airframe structures. The data have been taken from Defence Standard 00-970<sup>6</sup> and ASTM Handbook,<sup>7</sup> which should be consulted for more detailed information. [Table 4](#) indicates that with the 7000 series plate alloys, the susceptibility may be reduced by using a material in the over-aged T73 or T76 condition. In these tempers, however, the strength of the 7075 alloy is reduced by up to 10% compared with the peak aged T6 temper. The 7010 and 7050 alloys were developed to provide materials that matched the strength of the peak aged 7075 alloy and were resistant to exfoliation corrosion. Recent developments in both high-strength 7000 series alloys and damage-tolerant 2000 series alloys have been aimed at producing products with improved mechanical properties and a resistance to corrosion.<sup>8,9</sup>

The resistance of plate aluminum alloys to SCC is often assessed by determining a threshold stress below which failure will not occur. For this purpose, alternate immersion/emersion testing in 3.5% sodium chloride solution or outdoor marine exposure trials are conducted using C-ring or tensile bars cut from the plate material. [Table 5](#) gives typical values published in the literature for three commonly used plate materials. The susceptibility to SCC in these materials is orientation dependent and is mainly a consequence of grain shape. Plate materials are most susceptible when the stress is applied in the short transverse direction (ST) as shown in [Table 5](#). The

**Table 3** Exfoliation ratings applied to aluminum alloys

Rating	Description

effect of overaging the 7075 alloy to the T73 temper is to increase the SCC threshold stress from less than 55–300 MPa.

The data presented in Table 5 are derived from tests conducted on smooth specimens and basically relate to the initiation of stress corrosion cracks. The rate at which a stress corrosion crack propagates may also be studied. The usual approach is to determine the crack growth rate as a function of the stress intensity. A value of stress intensity  $K_{ISCC}$  can often be measured below which the crack does not grow effectively.

The threshold stress data and  $K_{ISCC}$  data are used together with service experience to assess the susceptibility of aerospace aluminum alloys to SCC. As discussed in the following section, susceptibility is dependent on the product form, that is, sheet, plate, tube, extrusion, etc., alloy composition, and the heat-treatment that has been carried out.

Data comparable to those available for exfoliation susceptibility are detailed elsewhere,<sup>6,7</sup> listing the SCC resistance of aluminum alloys. A similar rating system is employed as indicated in Table 6.

As previously discussed, the susceptibility to SCC in wrought aluminum alloys is orientation dependent. Plate aluminum–zinc–magnesium alloys heat treated to the T6 condition are particularly sensitive when loaded in the short-transverse (ST) direction. Heat treating material to the T73 and T76 tempers will improve the SCC resistance of an alloy such as 7075

from a 'D' to an 'A' or 'B' rating but with some loss in strength. The 7010 and 7050 alloys offer high strength and improved resistance to SCC. By applying a duplex ageing treatment, consisting of up to 24 h at temperatures in the range 120–135 °C followed by a shorter period at a higher temperature (160–170 °C),<sup>10</sup> the strength 7075 alloy in the T6 peak aged condition can be obtained but with much improved resistance to SCC. These alloys contain zirconium rather than chromium or manganese to inhibit recrystallization.

More recent developments in 7000 series airframe materials are described elsewhere.<sup>8,9,11</sup> Alloys such as 7449 are being considered in various product forms and tempers for use in upper wing skins, upper and lower wing stringers and wing box applications. The material gives improved strength combined with good resistance to corrosion.

#### 4.38.2.2.3 High strength steels

Steels employed in airframe manufacture fall broadly into the following groups:

- non-corrosion resisting mild steels and low alloy steels,
- intermediate alloy steels,
- high-alloy steels,
- precipitation and transformation – hardening steels (stainless).

The main concerns with high-strength steels are their susceptibility to hydrogen embrittlement (HE) and SCC. The wealth of available experimental data indicates that the mechanism of SCC in steels is one of hydrogen embrittlement. Hydrogen is generated during surface corrosion some of which will diffuse into the steel substrate.

Steels with ultimate tensile strength (UTS) levels up to 1100 MPa are considered to be immune to these forms of corrosion but above this strength level, the susceptibility increases as the UTS is raised. Under-carriage parts, for example, are often manufactured from low alloy steels such as 300M and AISI4340 that have strengths of 1800 MPa or above. Steels heat treated to these strengths are very susceptible to hydrogen embrittlement and SCC. In an identical way to that used for aluminum alloys, steels may be given an SCC rating of 'A' through to 'D.' Based on the guidance information given in Defence Standard 00-970<sup>6</sup>, the bar and tube product forms of 300M are given a 'D' rating, that is, very susceptible to SCC, while AISI4340 is less susceptible and has a 'C' rating. Within the four groups of steels, there are some variations in SCC susceptibility, but there is an overall trend showing that susceptibility increases with increasing UTS.

In selecting steels for aerospace applications, the tables given in Defence Standard 00-970<sup>6</sup> and ASTM Handbook<sup>7</sup> should be referred to in order to determine the potential SCC and hydrogen embrittlement risks. Where a choice of materials is available, the more corrosion-resistant materials should be selected. As discussed in [Section 4.38.2.3.3](#), steel parts must be protected against corrosion and wear. The choice of cleaning, pretreatment, and finishing processes available are greatly influenced by the SCC and HE susceptibilities.

#### 4.38.2.2.4 Magnesium alloys

The use of magnesium alloys is now largely limited to castings. Sheet alloys were used at one time for skinning on both fixed wing aircraft and on helicopters. Major corrosion problems were experienced in-service, particularly around fasteners where the protective treatments had cracked or flaked off. This resulted in reskinning programs replacing the magnesium alloy with sheet aluminum alloys. For many military applications, the use of magnesium alloy sheet is not permitted. Their lower density compared with aluminum alloys and their superior casting properties have made magnesium alloys particularly attractive for the production of gearbox housings for helicopter applications.

Unprotected magnesium alloys are susceptible to pitting corrosion but are not prone to intergranular attack. The presence of cathodic impurities such as iron, nickel, and copper has significant effects on the pitting behavior and improvements in corrosion resistance have been achieved by developing materials with lower impurity levels. The corrosion rate of a AZ91C magnesium–aluminum–zinc alloy, for example, may be reduced from 0.022 to 0.006 mm year<sup>-1</sup> in a marine–rural environment by lowering the iron level from 350 to 10 ppm.<sup>12</sup> In selecting magnesium alloys consideration should be given to choosing materials with lower impurity levels. Care must also be taken in processing materials in order to minimize the risk of surface contamination, which could initiate corrosion.

Some differences in corrosion behavior also exist between the main types of magnesium alloys employed for aerospace purposes. For example, the AZ63A magnesium–aluminum–zinc alloy has a corrosion rate of 0.018 mm year<sup>-1</sup> compared with a rate of 0.028 mm year<sup>-1</sup> for the EZ33 magnesium–rare earth–zinc alloy. For further information see ASTM Handbook<sup>12</sup> and manufacturer data sheets.

A key problem with magnesium alloys is the potential risk of galvanic corrosion when in contact with other materials. This requires the application of effective barrier coatings.

#### 4.38.2.2.5 Titanium alloys

Titanium alloys are relatively resistant to corrosion mainly due to the presence of a thin highly protective air formed oxide film. In terms of material selection there are no significant differences between the various types of titanium alloys to aqueous corrosion. However, the following points should be taken into consideration when selecting titanium alloys for airframe applications

##### *Galvanic corrosion*

Titanium alloys can promote galvanic corrosion when coupled to other airframe materials such as aluminum alloys, steel, and magnesium alloys. Precautions must be taken during assembly to reduce the contact between parts made from titanium alloys and other structural materials.

##### *Fretting corrosion*

Where small repeated movements take place between a titanium alloy part and parts made from either aluminum alloy or steel, there is a possibility that fretting damage may be induced in the titanium alloy surface. This can lead to early fatigue crack initiation. The risk of fretting can be minimized through the application of a suitable antifret surface treatment. A number of treatments are available commercially and include surface coatings and ion implantation treatments.

##### *Stress corrosion cracking*

While titanium alloys are generally resistant to both corrosion and SCC in marine environments, there are a number of chemicals and contaminants which are commonly found on aerospace structures that may induce corrosion and SCC.<sup>13</sup> These include chlorinated hydrocarbons, methanol and phosphate ester fluids at temperatures above 120 °C. It is good practice to avoid the use of titanium alloys in areas where contact with these chemicals is a possibility.

##### *Solid metal embrittlement*

Titanium alloys may be susceptible to solid-metal embrittlement when in contact with cadmium. Embrittlement may occur at ambient temperatures, but it is likely the embrittlement process that is accelerated at elevated temperatures. Failure of the component will take place under an applied stress if there is intimate contact between titanium alloy and cadmium plating.<sup>14</sup> For airframe applications, direct contact between cadmium and titanium should be avoided. At one time cadmium plating was often used on titanium alloy fasteners to improve lubricity and to reduce the

**Table 7** Methods currently employed in the protection of aerospace components

<i>Method of Protection</i>	<i>Examples</i>	<i>Applications</i>	<i>Substrate</i>

	Nickel plating	Electroless nickel plating	Steels Aluminum alloys
	Chromium plating	Hard chromium electroplating	Steels

likelihood of dissimilar metal corrosion when used with aluminum alloys. This practice is no longer permitted and cadmium plated steel parts and fasteners should not be in direct contact with titanium alloy parts.

Other metals that have been identified as causing solid-metal embrittlement under certain circumstances are zinc and silver.

#### **4.38.2.2.6 Composite materials**

While generally resistant to degradation from the chemicals employed on aircraft and to the environments to which aircraft are exposed, composite materials may contribute to the corrosion of other airframe materials. CFRP (carbon fiber reinforced plastic) composite materials behave in a similar manner to titanium alloys when coupled to less noble metals in so far as they will accelerate the corrosion of steel, aluminum alloys and magnesium alloys. There is also concern that some composite materials will absorb moisture, which may lead to the loss of mechanical properties.

### **4.38.2.3 Protective Treatments**

#### **4.38.2.3.1 Introduction**

Following manufacture, normal aerospace practice is to apply a protective treatment to parts made from aluminum alloys, magnesium alloys, and steels. Parts made from titanium alloys and composites may also be protected depending on the location on the airframe and environment to which the part is likely to

be subjected. The method of protection employed varies according to the substrate material as indicated in [Table 7](#).

In the following sections, the protective treatments applied to aerospace components are described in detail.

#### **4.38.2.3.2 Aluminum alloys**

##### **Current protective treatments**

The standard protective treatments currently applied to aerospace aluminum alloys are based on the use of chromate containing pretreatments and chromate pigmented primers. As indicated earlier, aerospace aluminum alloys are susceptible to localized corrosion particularly in the presence of chloride ions. Strontium chromate is a very effective corrosion inhibitor for aluminum alloys particularly on exposure to salt containing atmospheres. This is demonstrated by published data showing that, in 3.5% sodium chloride (a chloride level equivalent to that of seawater), the addition of  $0.02 \text{ mmol l}^{-1}$  of chromate is sufficient to prevent the onset of corrosion on a 2000 series aluminum alloy.<sup>15</sup>

[Figure 1](#) illustrates the protective scheme used on parts manufactured from aluminum alloys.

Prior to the application of the pretreatment, the part is degreased and cleaned using a suitable process such as alkaline degreasing, abrasive cleaning, organic solvent degreasing, and chromic–sulfuric acid etch. For fatigue critical parts it should be

**Figure 1** Standard protective treatment applied to aluminum alloy components.

noted that surface etching may have an adverse effect on fatigue life. Pretreatments normally used include chromic acid anodizing (CAA) and chromate conversion coatings (CCC). The purpose of these is to produce a protective film, which consists basically of alumina and, in the case of CCC, incorporates chromates and chromium oxide. In addition these coatings enhance paint adhesion by promoting mechanical keying.

CAA is usually conducted in a bath containing a concentration of 30–100 g l<sup>-1</sup> chromic acid. The anodizing voltage depends on the composition and temper of the alloy but is typically in the range 20–50 V. Times of up to 40 min are required to produce suitable films. Further details may be found in the appropriate process specifications. The anodic films produced by chromic acid anodizing consist of a thin barrier layer with a thicker porous outer layer. To achieve maximum paint adhesion, it is normal practice to paint within 8 h of anodizing. An alternative approach is to seal the anodic films prior to painting by immersing the part in near boiling water. This improves the protective properties of the film but probably at the expense of the paint adhesion.

Chromate conversion coatings fulfill the same role as anodizing but are generated by immersing the part in an acidic chromate bath. Details of the chemistry of the conversion coating process may be found elsewhere.<sup>16</sup> The films generated vary from colorless through yellow, iridescent, to brown depending on the film weight. The heaviest films, which are brown in appearance, are used when no further protection is to be applied. However coatings applied as a pretreatment for painting are normally yellow. Usual practice is to apply primer paint within 16 h of filming. A number of commercial treatments are available, which are approved to various aerospace and defense standards employed by the aerospace industry.

As indicated in **Figure 1**, the main protective treatment applied to airframe aluminum alloys is a chromate pigmented primer. In most instances, this will be a two-component epoxy paint but polyurethane primers are also used. One of the functions of the primer is to act as reservoir of strontium chromate corrosion inhibitor, which will be leached from the paint when the surface comes into contact with moisture. The presence of the inhibitor prevents corrosion from occurring at areas where the paint film has become damaged and the aluminum alloy is exposed. Laboratory experiments indicate that the amount of chromate leached out of the primer is well above the minimum concentration required to inhibit corrosion.<sup>15</sup> Primers used for aerospace applications are required to meet various performance criteria such as adhesion, resistance to fluids, corrosion, drying times, etc. For detailed information, specifications such as BS 2X33<sup>17</sup> or the equivalent European EN or US Military Standards should be consulted.

Epoxy primers have been employed on both civil and military aircraft for many years. Developments in the mid 1980s were concerned with improving the adhesion and fluid resistance of the standard primer. This was mainly in response to corrosion problems occurring on civil transport aircraft. Leakage of hydraulic fluids led to the degradation of the standard protective coatings and the eventual corrosion attack of the underlying aluminum alloy substrate. New generation primers were developed by leading aircraft paint manufacturers, which, in addition to giving improved resistance to aircraft fluids, gave better adhesion. Both types of primer are covered by standards such as BS 2X33. Normally the primers will be applied to components by spraying and this may be followed by a baking treatment.

Recent developments in primers have focused on reducing the level of solvents released. The primers originally used typically had a volatile organic

compound (VOC) emission level of  $600 \text{ g l}^{-1}$ . Within the European Union, legislation was introduced in the 1990s reducing the permissible levels of VOC in aircraft paints. For epoxy primers the level was set at  $350 \text{ g l}^{-1}$ . High solid primers are now available, which meet these requirements and have been applied to UK military aircraft.

The other area of concern is the formulation of chromate-free conversion coatings, anodizing treatments and primers. Chromates together with other hexavalent chromium compounds have been identified as carcinogens and the use of chromates in aerospace surface treatments and coatings is likely to be prohibited in the future. Several alternative treatments are available commercially but their use so far has been restricted to exterior surfaces on aircraft operating in benign environments. Progress towards chromate-free treatments includes the development of modified sulfuric acid anodizing processes, such as boric-sulfuric anodizing<sup>18</sup>; conversion coatings formulated using cerium salts, zirconates, vanadates, and molybdates; pretreatments based on sol-gel technology<sup>19</sup> and appliques<sup>20</sup> as potential replacements for conventional paint finishes. Several paint primer standards have been published covering chromate-free systems, which specify a range of corrosion performance requirements that will need to be fulfilled.

#### Aluminum coatings and cladding

In addition to chromate-based protective treatments, aluminum coatings are used for the protection airframe aluminum alloys. The coating may be applied by a physical vapor deposition (PVD) process or may take the form of a thin clad layer applied in the manufacture of the alloy. PVD aluminum coatings have sometimes been used to protect fatigue critical components.

Normal cleaning treatments such as chromic/sulfuric acid etching, and anodizing and chemical conversion pretreatments, often cause a reduction in fatigue strength, which may be as large as 10%. With PVD aluminum coatings, the surface is sputter cleaned prior to deposition and the loss in fatigue strength is small. Typically the aluminum coating is  $12\text{--}25 \mu\text{m}$  thick.

Clad sheet aerospace aluminum alloys are commercially available and find applications mainly in the construction of civil aircraft. The cladding is applied during the manufacture of the alloy and consists of a thin sheet of aluminum on either side of the alloy (see [Figure 2](#)). Typically the thickness of the cladding on each side is 5% of the total sheet thickness. For 2000 series aluminum-copper alloys, a commercially pure aluminum cladding is used while for 7000 series aluminum-zinc-magnesium alloys a aluminum-zinc cladding is employed. The cladding is corrosion resistant and isolates the alloy from the environment. Additionally, the cladding provides sacrificial protection if the underlying alloy becomes exposed as a result of surface damage. Clad alloys have lower strengths than the equivalent unclad material and are less resistant to fatigue damage. As a result, they tend not to be selected for use on military aircraft. Depending on the operating environment, parts made from clad materials may be further protected using the standard scheme outlined earlier.

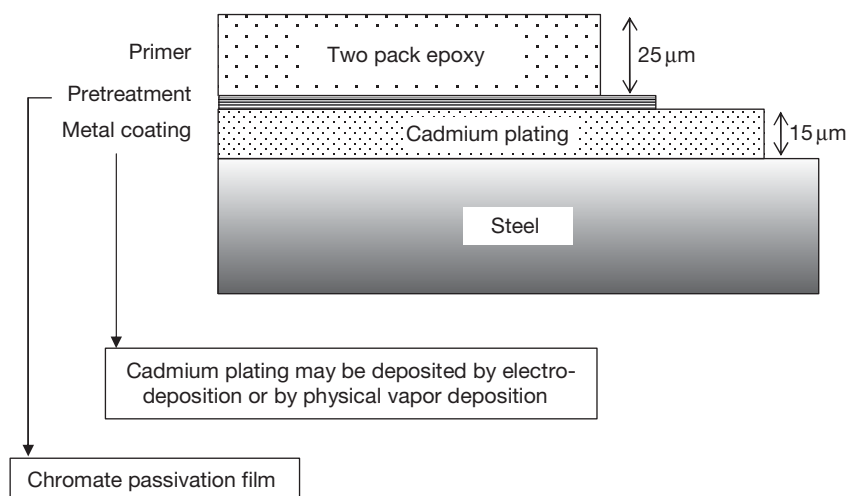

#### 4.38.2.3.3 Steels

For most applications, passivated cadmium plating is the preferred protective treatment for high-strength and corrosion-resistant steels. [Figure 3](#) shows schematically the protective coating applied to steel parts.

Cadmium plating offers a unique range of physical and mechanical properties, which are so far unmatched

**Figure 2** Structures of clad 2000 and 7000 series sheet aerospace aluminum alloys.

**Figure 3** Standard protective treatment applied to steel components.

by other protective treatments. Cadmium provides a sacrificial coating that is galvanically compatible with aerospace aluminum alloys and has a high lubricity. The latter is an important property when the coating is used on fasteners or threaded parts.

The coating is normally applied by electrodeposition from a cyanide-based plating bath, which permits dense uniform coatings to be deposited on to complex surfaces with threaded areas, recesses, etc. The thickness of cadmium required is dependent on application. Defence Standard 03-19<sup>21</sup> proposes that for normal requirements on noncorrosion resisting steels a minimum average thickness of  $14\text{ }\mu\text{m}$  should be employed, while for threaded items a minimum average thickness in the range  $4\text{--}7.5\text{ }\mu\text{m}$  depending on the nominal average thread diameter is necessary.

Like most electrodeposition processes, cadmium plating is less than 100% efficient and significant levels of hydrogen may be generated. As discussed earlier, high-strength steels are susceptible to hydrogen embrittlement and the susceptibility increases with increasing UTS. Following plating, a de-embrittlement baking treatment is conducted, which reduces the level of hydrogen.

For processing purposes, high-strength steels may be divided into four strength categories as follows:

- Category 1 up to 1100 MPa
- Category 2 1101–1450 MPa
- Category 3 1451–1800 MPa
- Category 4 1801 MPa and greater

Steels falling into the category 1 are not considered to be susceptible to HE and a baking treatment

is not regarded as necessary. For steels in category 2, a minimum post plating treatment of 8 h at  $190\text{--}230\text{ }^{\circ}\text{C}$  is employed. For categories 3 and 4, the minimum baking times are increased to 18 and 24 h respectively. In addition to determining the baking conditions, the range and types of cleaning treatments, which may be carried out prior to plating, are dependent on the strength category. As the UTS of the steel increases, processes that may generate hydrogen should be avoided.

For steels with category 3 or 4 strengths some constructors prefer to use cadmium plating prepared by PVD. This is a nonaqueous process involving the deposition of cadmium by evaporation within a vacuum chamber.

After plating, a chromate passivation treatment is applied to improve the corrosion resistance of the cadmium and to act as a pre-treatment for subsequent painting. The process is carried out by immersing the part in a bath containing a sodium dichromate/sulfuric acid solution to produce a yellow film. Fasteners are used in the plated and passivated condition while components are normally primed before assembly.

In situations where parts may become heated to temperatures above  $230\text{ }^{\circ}\text{C}$ , zinc plating may be used rather than cadmium plating. Areas that are difficult to electroplate, for example, the internal bore of a tube, are sometimes phosphated rather than plated.

The main problem with cadmium plating is the toxic nature of cadmium compounds, which can cause fetal damage as well as damage to the kidneys, lungs, and liver. Legislation banning the use of

**Table 8** Possible alternatives to cadmium plating

Coating type	Coating composition	Method of application	Major limitations
Aluminum based	Aluminum	Physical vapor deposition	Plating in recesses/holes may be difficult Limited commercial availability
	Aluminum	Electrodeposition from an organic bath	
Zinc based	Aluminum–manganese	Electrodeposition from molten salt bath	Not generally available
	Zinc–nickel (low)	Electrodeposition	Commercially available
	Zinc–nickel (high)	Electrodeposition	Post plating treatments such as hydrogen de-embrittlement and passivation required.
	Zinc–cobalt	Electrodeposition	Limited coating lubricity
Metallic–ceramic	Zinc–cobalt–iron	Electrodeposition	Tend to be thick coatings – generally unsuitable for fasteners
	Al and Zn flakes in an inorganic matrix	Electrostatic spraying, dipping or spin coating	
Manganese based	Manganese alloys	Electrodeposited	Limited availability commercially – mainly laboratory processes. Low bath efficiencies

cadmium plating for many engineering applications was introduced within the European Union some years ago but its use on aircraft components is still permitted. Continuing concerns about the harmful effects of cadmium has led to a number of studies aimed at identifying possible replacements. While it is unlikely that a single replacement coating will be found, a number of coatings are available commercially that could be used as alternatives to cadmium plating for specific applications. **Table 8** details the range of coatings that have been considered together with some of their limitations.

The coatings fall into four groups, all of which provide a level of sacrificial protection. The aluminum- and zinc-based coatings are normally given a passivation treatment after plating to improve the corrosion resistance. These tend to be chromate solutions but some nonchromate treatments are now becoming available. The metallic–ceramic coatings group covers several commercially available types consisting of an inorganic matrix incorporating aluminum or zinc flakes or powders. The feasibility of electrodepositing manganese alloy coatings was demonstrated more than 60 years ago, but it is only relatively recently that their use as alternatives to cadmium plating has been investigated. In some instances, the alternative coatings are thicker than the cadmium plating in order to achieve the same level of protection.

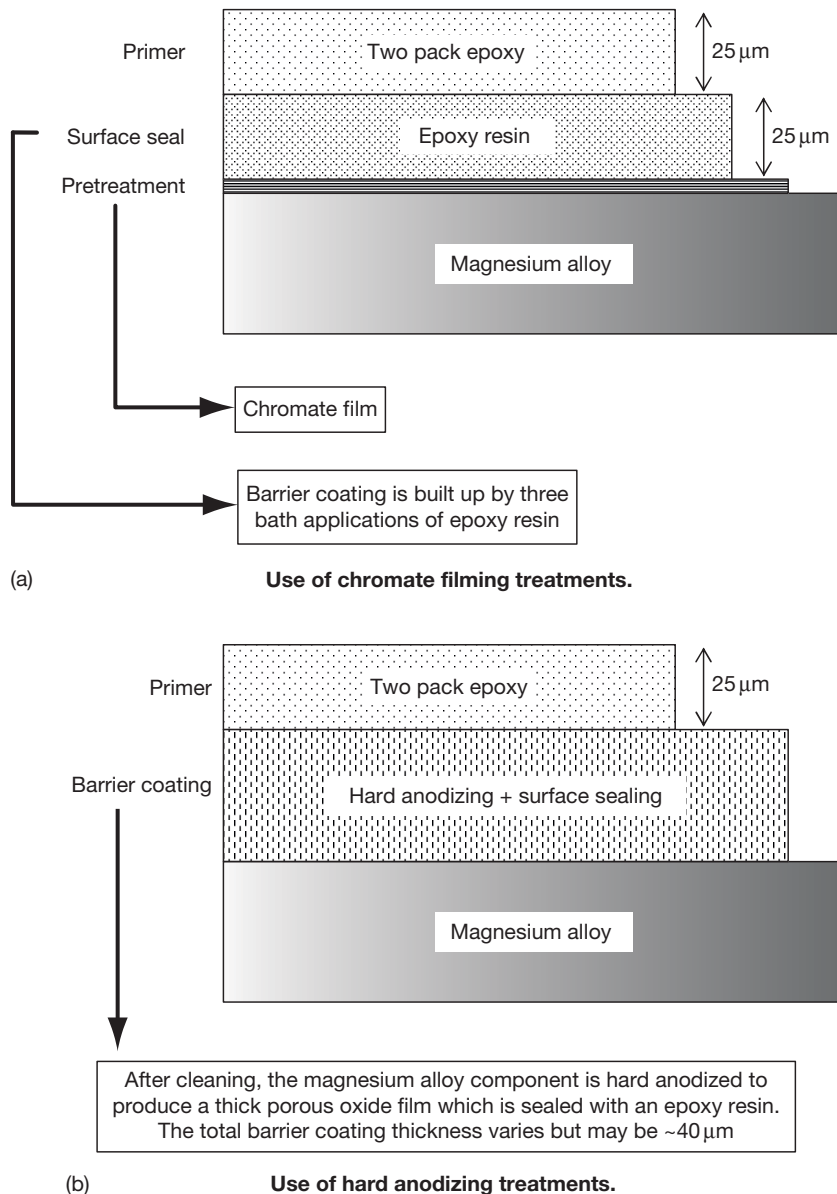

The results of a number of major programs examining alternatives to cadmium plating for aerospace applications are available in the literature.<sup>22–24</sup> In addition to the corrosion aspects of alternative coatings, other important properties such as lubricity,

torque–tension behavior, hydrogen embrittlement, effects on fatigue, paint adhesion, and coating repair have been investigated. Depending on the particular application, some of these aspects must be taken into account when selecting an alternative coating system. Some general guidance on cadmium replacements can be found elsewhere.<sup>25</sup>

#### 4.38.2.3.4 Magnesium alloys

The normal approach adopted for the protection of parts made from magnesium alloys is to isolate the component from the environment through the use of a barrier coating. The standard protection scheme consists of a nonpigmented epoxy resin as indicated in **Figure 4(a)**. The part to be protected is first cleaned to remove all traces of contamination. The cleaning processes employed include solvent and vapor degreasing, mild alkaline treatments, and various acid pickles. Fluoride anodizing is also employed as a cleaning treatment. The part is anodized in an ammonium bifluoride solution using alternating current to produce an anodic film. This is removed by immersing the part in chromic acid to leave a surface free of contamination.

Prior to carrying out the sealing treatment, a chromate filming treatment is applied to the component to improve the corrosion resistance and promote the adhesion of the epoxy resin. Generally, a thick layer of resin is applied by dipping the component which has been preheated to around 200 °C into a bath maintained at 60 °C containing the resin solution. After removal from the bath, the resin is stored at 180 °C for 45 min. The process is repeated three times to build up a resin thickness of about 25 µm.

**Figure 4** Examples of protective treatments applied to magnesium alloy components.

As indicated in [Figure 4](#), two pack epoxy primer paint is applied to the part before assembly.

Several new protective processes have been introduced using anodizing treatments, an example of which is given in [Figure 4\(b\)](#). These have been adopted by several manufacturers for the protection of gearbox housings. The anodizing treatments generate films which are up to  $40\ \mu\text{m}$  thick and which may be subsequently surface sealed.

Other protective treatments, which either have been used or are being considered for magnesium

alloy parts, include metallic–ceramic coatings and thick hard anodic films formed by high voltage anodizing.

#### 4.38.2.3.5 *Titanium alloys*

As previously stated, titanium alloys have a high resistance to corrosion in the presence of moisture and most of the contaminants found within the aircraft structure. If used in isolation, titanium alloy parts require only the minimum in terms of corrosion protection. This could be a single coat of primer

**Figure 5** Protective treatments that may be applied to titanium alloy components.

applied to the surface of the component as indicated in [Figure 5](#).

To promote paint adhesion, the surface would normally be cleaned using a mild wet abrasive treatment or a pickling solution. Etch primers and anodizing treatments are also sometimes used. The main problem with titanium-based alloys arises when contact is made with other metals and precautions must be taken to reduce the risk of galvanic corrosion. Zinc plating or zinc shims are often employed for this purpose when contact has to be made with magnesium alloy parts.

#### 4.38.2.3.6 Composite materials

Composite materials used in the manufacture of airframe parts and panels do not suffer corrosion degradation but items made from plastics reinforced with carbon fiber may have an adverse effect on the corrosion of some metal parts with which they are in direct contact. Measures that should be taken to minimize this risk are described in [Section 4.38.2.4](#) dealing with the design and assembly aspects of corrosion management.

Where a part made from composite materials is being used internally, surfaces may be left untreated. Where the part forms part of the external surface of the aircraft, a suitable pretreatment is applied followed by a paint scheme consisting of a primer and top coat. As a pretreatment, mechanical scuffing followed by degreasing is adequate if an epoxy primer is to be used. Since the paint is not providing corrosion protection to the composite substrate a chromate-free epoxy primer or epoxy filler may be employed.

#### 4.38.2.3.7 Wear and fretting resistant coatings

In locations where there may be some movement or rubbing between parts it is often necessary to use a coating or surface treatment to minimize the risk of fretting or wear developing. Examples include landing gear components and flight control actuators.

Electroless nickel and hard chromium coatings are often employed for this purpose particularly on steel parts and hard anodizing is sometimes used on aluminum alloys. Specialized treatments such as ion implantation and high voltage anodizing are also available and are beginning to find applications on airframe parts. Metal coatings such as electroless nickel and hard chromium plating while primarily used to reduce wear or fretting do provide some level of corrosion protection. The coatings act purely as a barrier layer, which isolates the substrate from the environment. Generally, these coatings are much thicker than cadmium, aluminum, and zinc plating, but provide no sacrificial protection once the substrate is exposed. Developments in wear resistant coatings have mainly been concerned with the incorporation of fine ceramic particles into electrodeposited coatings and the deposition of hard metal sprayed coatings. To some extent this has been driven by the need to replace hard chromium and eventually nickel coatings with environmentally compliant treatments. Sartwell *et al.*<sup>26</sup> describes recent research assessing the use of HVOF thermal spray coatings on landing gear.

#### 4.38.2.4 Design Considerations

Careful design of the airframe to prevent the buildup and ingress of moisture and other corrosive agents into the structure will prevent the development of several potentially damaging and expensive corrosion problems. This can be achieved through the use of drain holes or filler materials in areas where moisture could collect. Sealing joints will also greatly reduce the risk of both crevice and dissimilar metal corrosion. [Table 9](#) lists some of the potential corrosion problem areas and the design approach to reducing the risk.

In the case of dissimilar metal contacts, guidance material is available from several sources, including PD 6484:1979<sup>27</sup> and US Military Standard,<sup>28</sup> enabling potential problem areas to be identified. The corrosion between different metal couples is rated by the degree to which the corrosion of one metal is increased by contact with a second. For example, if a titanium alloy is in contact with an aluminum alloy, the corrosion of the titanium alloy is not increased but the corrosion of the aluminum alloy is markedly increased.

[Table 10](#) details some of the dissimilar metal contacts that are likely to cause corrosion problems and gives examples of procedures, which may be employed to minimize the risk. In the examples given, there is a marked increase in the corrosion

rate of the more active material due to the large difference in corrosion potential between the two metals. In order to reduce the risk of corrosion occurring, parts are protected and assembled to prevent metal-to-metal contact.

Experience has shown that many of the corrosion problems found in-service are often in internal areas that are difficult to inspect. Access for examination is an important design consideration, which will reduce inspection times and costs.

**Table 9** Examples of potential corrosion problems and possible design solutions

<i>Potential problem</i>	<i>Design solutions</i>
Crevices	Static joints should be sealed to eliminate crevices – May be achieved by the use of wet assembly
Dissimilar metal contacts	Metal coatings, shims, wet assembly to reduce differences in galvanic potential and electrically isolate parts
Water traps	Incorporation of a drainage scheme to prevent the accumulation of fluids. Consideration of the inclusion of drain holes and the use of inert fillers
Leakage from galleys and toilet areas.	Use of non-metals, drain paths, sealed floor coverings

#### 4.38.2.5 Final Assembly and Finishes

As discussed in [Section 4.38.2.3](#), it is normal practice to apply an appropriate protective treatment to all parts prior to assembly. Where necessary, additional procedures will be carried out to reduce the risk of dissimilar metal corrosion as outlined in [Section 4.38.2.4](#). In general, wet assembly methods will be employed to prevent the ingress of moisture at joints and prevent the occurrence of crevice and dissimilar metal corrosion. As indicated, certain areas within the fuselage, wings, undercarriage bay, and tail plane may be especially prone to the collection of aircraft fluids, leakage from galleys and toilets or to the build up of moisture and corrosive contaminants. These areas will require additional protection during assembly such as a further epoxy primer coat or a finish coat. One approach described by Voss<sup>29</sup> is to divide the aircraft structure into zones. In the example given, a military fast jet, three zones were identified as follows:

- Zone A – Interior surfaces, not to be subjected to permanent condensation
- Zone B – External and internal surfaces, to be exposed to wet condensation
- Zone C – Fuel wetted surfaces

For areas falling into the Zone A classification further protection is not necessary. For Zone B, some additional protection is applied, for example,

**Table 10** Corrosion at dissimilar metal contacts and assembly procedures to be employed

<i>Contact</i>	<i>Corrosion</i>	<i>Protective treatment</i>	<i>Assembly</i>
Corrosion resisting steel coupled with Aluminum alloy	No increase in corrosion rate Corrosion rate may be markedly increased	Cadmium plating + Painting (optional) Pre-treatment + primer	Wet assembly
Corrosion resisting steel coupled with Magnesium alloy	No increase in corrosion rate Corrosion rate markedly increased	Cadmium plating + painting Full protective scheme	Wet assembly
Titanium alloy coupled with Magnesium alloy	No increase in corrosion rate Corrosion rate markedly increased	Zinc or aluminium coating + painting Full protective scheme	Wet assembly
Titanium alloy coupled with Aluminum alloy	No increase in corrosion rate Corrosion rate markedly increased	Painting or aluminium coating Pretreatment + primer	Wet assembly
Titanium alloy coupled with High strength steel	No increase in corrosion rate Corrosion rate markedly increased	None required Coated with Al, Al rich coating or cadmium	Wet assembly
Carbon fiber reinforced composite coupled with Aluminum alloy	No corrosion Large increase in corrosion rate	Pretreatment + primer Standard protective scheme	Adhesive bonding or wet assembly

a polyurethane finish coat while in areas such as fuel tanks (Zone C) special sealants and paint schemes need to be employed. If there is a risk of microbial corrosion occurring, the use of paints containing a biocide might be considered.

The normal finish coat employed is a two pack polyurethane paint. Polyurethane finishes have been available for aerospace applications for many years and continue to be widely used on both civil and military aircraft. As indicated in [Section 4.38.1.2](#), one of the main sites for corrosion initiation is around fasteners on external surfaces where the development of cracks in the paint film allows the ingress of moisture. One of the important advances in polyurethane finishes has been the formulation of paints with increased flexibility, which are less prone to cracking. Current specifications for polyurethane finishes<sup>30</sup> identify two types of materials one intended for interior and exterior use where the maximum resistance to fluid attack is required and one intended for exterior use where increased tolerance to flexing is needed.

Acrylic finishes were used on some military aircraft for a number of years. They were introduced in the 1970s partly to fulfill a requirement for a paint scheme, which could be more readily removed than polyurethane finishes. The latter are highly resistant to fluids and very aggressive paint strippers must be employed to remove the polyurethane finish. The life of the acrylic finishes is relatively short (2 years) compared with polyurethane schemes (5 years) and the trend has been to phase them out in favor of polyurethane finishes.

The external painting of an aircraft is not solely for corrosion protection purposes. On military aircraft, the finish coat is used for camouflage purposes while on civil aircraft it is used to identify the airline or operator. On large transport aircraft, the paint applied to the external surfaces makes a significant contribution to the overall weight, which in turn will have an impact on fuel costs, passenger numbers, etc. Boeing<sup>31</sup> estimate for a 747-400 the weight of the paint applied to the fuselage and tail is approximately 252 kg. Some airlines have preferred to operate aircraft with polished rather than painted skins. In these cases, clad aluminum alloys are used for the skinning and the surface is treated with a clear conversion coating. Boeing has calculated that the fuel cost savings are offset by the higher costs of washing and polishing unpainted aircraft.

On some areas of the aircraft, specialized finishes may be employed. These include walkways, high temperature areas around engines and radome surfaces. For further information on these finishes,

national and international specifications as well as manufacturer data sheets should be consulted.

### **4.38.3 Corrosion Management In-Service**

#### **4.38.3.1 Introduction**

During the manufacture of an aircraft, the procedures broadly outlined in [Section 4.38.2](#) are applied to produce a structure that is resistant to corrosion degradation. The approach is based on the selection of materials with a good resistance to corrosion, the application of protective treatments to individual components, and careful design to avoid potential corrosion problems. The airframe is wet assembled using sealants, jointing compounds, etc. to prevent moisture ingress into joints and other parts of the structure. External surfaces and internal areas, likely to suffer high levels of moisture build up or leakage of aircraft fluids, are given further protection by painting with a primer or a finish coat. In-service protective treatments can become degraded or damaged; drain-holes and drainage systems may be blocked and changes in operational role and life extensions can subject the airframe to environments for which it is not adequately protected. Corrosion management in-service is therefore concerned with maintaining the integrity of the aircraft throughout its operational life. It includes the cleaning and washing of exterior surfaces to remove harmful contaminants, inspecting for early signs of corrosion, corrosion rectification, the application of supplementary protective coatings, and the repainting of aircraft.

#### **4.38.3.2 Aircraft Washing and Cleaning**

Lewin<sup>32</sup> has described in some detail the way in which corrosive contaminants may build up on the surface of aircraft in-service. For example, during normal maneuvering on the ground, the exterior surfaces of aircraft may become covered with dust and salt, which may mix with moisture to form a clay-like structure, which adheres to the aircraft exterior. In-flight Lewin suggests that electrostatic forces generated will cause light dust to be deposited on aircraft skins. In addition engine contaminants such as oils, fluids, and carbonaceous films form on surfaces. If these contaminants are not removed from the aircraft surface, they will contribute to the eventual breakdown of the protective coatings and corrosion of the airframe.

Freshwater rinsing is often used on military to reduce levels of chloride and other contaminants

present following maritime operations. Land-based aircraft may taxi through dedicated spray units on landing to remove surface salt.

Aircraft cleaning is generally carried out by first flushing exterior surfaces with water to remove loose dirt or other residues. The cleaning solution is sprayed on to an area of the aircraft and soft brushes may be used to remove surface contaminants. The area is then rinsed with fresh water and a new area cleaned. At the end of the cleaning operation, the whole aircraft is rinsed with water and dried off. Various types of cleaners approved for aerospace applications are available commercially. National standards identify different types of cleaners designed to remove different levels of contamination. Part of the approval process involves subjecting the cleaners to different corrosion tests to ensure that they will not cause damage to the airframe and engine materials.

#### 4.38.3.3 Inspection for Corrosion

The early detection of corrosion remains a major priority for the in-service management of corrosion. At present, much reliance is still placed on visual inspection, often with hand lenses, looking for evidence of paint blistering, paint cracking, and filiform corrosion, particularly around fasteners. For internal areas where access is difficult, mirrors and endoscopes may be employed to facilitate the visual inspection. In some instances, the paint is removed from structurally critical areas to allow the metal substrate to be examined more thoroughly.

Many of the areas on an aircraft are difficult to inspect visually without dismantling parts of the airframe structure. The early stages in the development of corrosion and fatigue in fuselage lap joints present on many older transport and military aircraft, for example, are almost impossible to detect visually. To that end, nondestructive evaluation (NDE) techniques employing ultrasonics, eddy current measurements, radiography, and thermography are being employed to search for the evidence for the onset of corrosion and fatigue damage. NDE techniques are also used to assess the extent of the corrosion damage on hidden surfaces and to determine the depth of corrosion and the remaining wall thickness. This information is crucial in deciding the manner in which specific corrosion problems should be managed. Much research into developing improved NDE techniques for the early detection of corrosion is in progress.

The frequency and level of inspection undertaken vary according to the aircraft type and examples for

civil transport aircraft are given elsewhere.<sup>33,34</sup> On a daily basis, areas would be examined for evidence of fuel leaks, cracking, surface damage, etc. Every 4 or 5 days, a more detailed visual inspection would be carried out of the interior and exterior surfaces and at longer intervals (typically 30 days) access panels may be removed to allow inspection of specific areas. Inspections employing NDE techniques are generally carried out at 12–18 month intervals, and every 3–5 years major checks involving removal of interior panels are conducted to allow careful examination of structural parts for signs of corrosion and cracking.

#### 4.38.3.4 Corrosion Rectification

##### 4.38.3.4.1 Corrosion removal

At present aircraft operators adopt a ‘find-and-fix’ approach to airframe corrosion. Often corrosion and fatigue damage are found during the scheduled maintenance of the aircraft. The occurrence of damage in a particular location may necessitate a fleet-wide inspection for similar damage on other aircraft.

With the find-and-fix approach a repair scheme is implemented, as soon as practical. The extent and depth of the corrosion that is found will determine whether a repair can be made, whether components must be replaced, and the time-scale in which they must be carried out. For aerospace structures, three levels of corrosion have been specified and are detailed elsewhere.<sup>35</sup> Level 1, for example, refers to relatively minor corrosion damage found between inspection periods that may be blended out within the limits specified by the manufacturer. Level 2 is concerned with corrosion that requires work or blending out which exceeds the manufacturer’s limits, while level 3 corrosion is sufficiently serious that there are urgent airworthiness implications.

For corrosion damage falling within ‘Level 1,’ repair often involves the blending away of corrosion damage, probably using a combination of mechanical and chemical methods, and then applying a protective coating to the blended area. Typically the allowable limits are 10% of the thickness for wing and fuselage skins. Mechanical methods commonly employed include rubbing with metal wool, abrasive pads or small abrasive wheels, and abrasive blasting with glass beads or alumina grit. Portable abrasive blasting units are available, which allow corrosion removal to be carried out *in situ*. The units recycle the spent abrasive and separate out the corrosion products.

When the corrosion found exceeds the allowable limits (Level 2), it may be necessary to replace

components or carry out a structural repair. For corrosion damage identified as 'Level 3,' other similar aircraft in the operator's fleet would be inspected and the findings reported to the appropriate regulatory authority.

Problems may arise when corrosion occurs on areas that have already been blended and reprotected. This may result in the total depth of corrosion exceeding the allowable limits set by the manufacturer.

#### 4.38.3.4.2 Reprotection

Once the corrosion has been blended out, the metal surface is reprotected using a suitable protective scheme. Often it is not possible to apply the original scheme, but rather a modified treatment. [Table 11](#) gives examples of repair schemes that are employed to various substrates.

For aluminum alloys it is normal to use a conversion coating as a pretreatment for painting. The use of etch primers for the repainting of the air intake of an aircraft following paint stripping and removal of the corrosion damage has been described.<sup>36</sup> In this instance, an etch primer was chosen as the pretreatment rather than the normal chromate conversion coating. The choice was made to avoid the need to deoxidize the surface and water rinse the intake before and after the application of the conversion coating. There was concern that aggressive solutions could have been washed into the internal structure of the aircraft.

Small areas of damage on cadmium plated steel parts may be repaired after removal of corrosion products using an approved paint scheme. Brush plating techniques allow the localized repair of small areas of damaged coatings such as zinc, nickel, and cadmium electroplating. The process depends on the establishment of a plating cell between an anode (usually a graphite rod) wrapped in an absorbent material saturated with electroplating solution, and the damaged area, which is the cathode. During plating, the anode is rapidly moved backwards and forwards over the damaged area in order to build up a

uniform deposit. Often brush plating may be carried out *in situ* greatly reducing the cost of corrosion rectification. One aerospace application has been the repair of damaged cadmium plating on landing gear components. High-efficiency solutions are available, which greatly reduce the risk of hydrogen evolution and absorption. After plating the cadmium plating is passivated and then painted with an appropriate paint scheme. The repair of cadmium replacement coatings such as electroplated zinc alloy and PVD aluminum is an area that is currently being studied.

As described in [Section 4.38.2.3.4](#), the protection of magnesium alloy components involves a series of complex cleaning and coating procedures. When extensive corrosion is found, the component must be removed from the aircraft and where possible disassembled. After cleaning using some form of abrasive blasting to remove corrosion products and degraded resin, the magnesium parts are reprotected using the schemes outlined in [Section 4.38.2.3.4](#). If the corrosion found is limited to a few small areas, it may be possible to repair *in situ*. This involves removing any damage mechanically, and then cleaning chemically using an acid chromate solution. The area is then repainted with a primer and top coat. More detailed information on procedures that should be undertaken is given in national and international standards.

The protective finishes applied to the top and lower wing skins play an important role in preventing the initiation of localized corrosion within fastener countersinks and in fastener holes. As discussed in [Section 4.38.2.5](#), epoxy primers and polyurethane finishes with improved flexibility are available, which reduce the occurrence of cracking around fasteners and prevent the ingress of moisture. In some instances these coatings have not been found to give adequate protection, and alternative protective schemes using self curing polysulfide elastomeric coatings have been employed. These may be used directly as a primer or

**Table 11** Examples of protective schemes used in the repair of damaged coatings

Substrate	Original protective treatment	Repair schemes
Aluminum alloys	Chromic acid anodizing or chromate conversion coating + epoxy primer (+finish coat)	Swab applied conversion coating + coat of primer paint (+finish coat) Etch primer + coat of primer paint (+finish coat)
Steels	Cadmium plating + passivation treatment + primer + finish coat	<i>In situ</i> repair using low HE cadmium brush plating + passivation and paint scheme
Magnesium alloys	Pretreatment + barrier coating + paint scheme	Etch primer + 2 coats of primer + finish coat

alternatively may be applied over a conventional epoxy primer. The elastomeric coatings are typically 150–250  $\mu\text{m}$  equivalent to a coating weight of 270  $\text{g m}^{-2}$  compared with a weight of 70  $\text{g m}^{-2}$  for standard schemes. For this reason the coatings are used selectively, for example, along fastener runs, rather than over the whole surface to minimize the weight penalty. After applying the polysulfide coating the surface is painted with a flexible polyurethane finish.

#### 4.38.3.5 Use of Supplementary Protection

The corrosion repair of internal areas may prove a much greater challenge requiring parts of the structure to be broken down to permit access for rectification to be carried out. In such cases, it may be possible to control the corrosion by applying a supplementary protective coating. These function by forming a barrier layer, which separates the substrate from the immediate environment. Several types are available commercially, which may be used on aircraft structures. These may be applied by brushing or spraying. Some of the products have water displacing properties, which leave a thin oily film after the solvent has evaporated, while other products must be applied to dry surfaces and produce a wax-like coating. At best supplementary protection will prevent the further spread of corrosion and may enable rectification work to be delayed to a time when the aircraft is undergoing major servicing.

#### 4.38.3.6 Paint Removal and Repainting

The polyurethane finishes that are widely employed on the external surfaces of civil and military aircraft are highly resistant to fluids and are generally effective for up to 5 years. In-service, the paint films are subjected to large fluctuations in temperature, exposure to high levels of UV radiation, flexing during flight, and exposure to aggressive environments, leading to the crazing, cracking, and degradation of external paint schemes. For many years, the polyurethane paint schemes could only be removed for repainting or inspection purposes by using aggressive chemical paint strippers many of which were based on methylene chloride with a phenol additive. These materials are extremely hazardous to use, posing many health and safety issues.

Mechanical methods of paint removal such as plastic media stripping (PMS) are now extensively used. In the PMS process, small plastic beads are impacted onto the painted surface causing the paint

film to crack and flake off from the substrate. Commercially available equipment allows the plastic beads to be blasted at the work surface at a controlled velocity and to recycle spent beads removing dust and paint particles. Some operators and maintenance organizations have installed facilities that allow small components as well as complete aircraft to be stripped. There are some limitations in place regarding use of PMS on thin metal sheet, clad alloys, and composite materials. Other blasting media such as dry ice and wheat starch have been evaluated. There is also interest in laser techniques, possibly for removing paint in around fasteners.

Another approach employed to simplify paint removal has been the use of selectively removable paint schemes. These permit the polyurethane top coat to be removed while leaving the primer intact. The schemes use 8–12  $\mu\text{m}$ -thick intermediate coats, which are painted over the epoxy primer. The polyurethane finish is then applied to the intermediate coat. A comparatively simple paint stripper may be used to remove the finish and intermediate coats, but leave the primer intact. The use of such schemes on commercial aircraft has been described.<sup>37</sup> Aerospace paint standards have been issued covering both the intermediate coating<sup>38</sup> and the paint remover.<sup>39</sup>

#### 4.38.3.7 Dehumidification

The corrosion found on an aircraft occurs mainly when it is parked on the ground or sitting in a hangar. Aircraft operated by the civil airlines spend a high percentage of their time flying, while many military aircraft are designed with a low number of flying hours but are required to remain operational for many years. In addition, many military airfields are very close to the coast and at these locations the atmosphere may be very corrosive.

The rates of corrosion of many airframe alloys exposed to the atmosphere are dependant on the relative humidity (RH), that is, the amount of moisture present in the air. There is often a critical RH typically  $\sim 50\%$  above which the rate of corrosion increases rapidly with increasing RH. Below this critical RH, the corrosion rate is low and diminishes to an insignificant level when the RH is reduced to 10% or less. To reduce the risk of corrosion, dry air dehumidification has been employed to lower the humidity within the aircraft to less than 10% RH. Examples are given in the literature of both complete and partial dehumidification being employed in the management of military aircraft.<sup>40,41</sup> In some

instances, localized dehumidification has been used to reduce the risk of corrosion in areas where electronic equipment is housed, on turbines, and parts of the airframe especially susceptible to corrosion. Whole aircraft dehumidification using dedicated shelters has now become a regular procedure for maintaining both fixed wing aircraft and helicopters.

#### 4.38.3.8 Future Trends in Aircraft Corrosion Management

In-service aircraft structures are subjected to both fatigue and corrosion degradation. While the damage due to fatigue is primarily a function of the number of flights and the number of flying hours, corrosion is more closely related to the physical age of the aircraft. Many of the protection schemes applied to the internal areas of the fuselage and wings when the aircraft was built cannot be renewed without carrying out major dismantling of the airframe structure. Primer paints, for example, applied during the initial build are expected to provide corrosion protection throughout the life of the aircraft. Often these will become damaged or degraded due to the leakage of aircraft fluids or the build up of condensation and moisture. As the operational life of the aircraft is extended, the probability of corrosion developing is greatly increased.

Many of the aircraft currently in-service have exceeded their design operational life. This applies to both military and civil aircraft. Statistics published in 2000<sup>42</sup> indicated that more than 2500 commercial aircraft in the United States were flying beyond their 20-year design life. Figures published by the US Federal Aviation Authority suggested that 7% of the aircraft, which would be covered by the proposed Aging Airplane Safety regulation, are more than 40 years old. As the operational life of an aircraft is extended, there are increased maintenance costs. For example, statistics published for USAF aircraft<sup>43</sup> show that the total cost of corrosion rose from \$926 million in 1990 to \$1518 million in 2004 despite a reduction in fleet size.

The present find-and-fix approach to aircraft corrosion management is expensive both in terms of cost and the time aircraft are taken out of service. Two organizations, the United States Air Force and the Australian Department of Defence, have proposed changing from the find-and-fix approach<sup>44,45</sup> to a more structured method of managing corrosion. The alternative approaches, described as 'anticipate-and-manage' by USAF<sup>44</sup> and 'identify-and-manage' by the Australian DoD,<sup>45</sup> have similar aims of

lowering maintenance costs and reducing aircraft nonavailability times. These aims may be achieved by rescheduling corrosion rectification work where possible so that it is carried out during normal servicing and maintenance periods.

To implement the new approaches to corrosion management, a number of areas have been identified where improvements in current technology are required. These include more sensitive methods for detecting corrosion, the development of a better understanding of the impact of corrosion on structural integrity, and more effective supplementary protective materials to halt the spread of corrosion.

To detect the early stages of corrosion, improved NDE methods are required together with corrosion sensors to locate the onset of corrosion in 'difficult-to-inspect' areas. It has been proposed that sensors should be installed in potential corrosion problem areas within an aircraft during its manufacture. These would permit the first signs of corrosion to be detected and its progress to be monitored. In parallel with improved detection, there is a need for accurate, reliable models for predicting the long-term effects of corrosion on fatigue and static strength. These would allow decisions to be made concerning the scheduling of inspections and corrosion rectification. The application of better supplementary protection would further allow work to be delayed until programmed maintenance periods.

The new approaches to aircraft corrosion management are aimed at lowering the cost of ownership by reducing the time spent on unscheduled maintenance.

rapid and affordable construction of the much needed infrastructure in postwar Europe, but as discussed in the **Chapter 3.30, Degradation of Cement and Concrete** in this book, such materials are not without their own durability problems and corrosion risks.

### 4.39.2 Causes of Degradation

#### 4.39.1 Introduction

The term ‘infrastructure’ covers a wide range of industries involved in establishment and maintenance of an effective and functional industrialized society. These include structures such as bridges and tunnels for road, rail, and canal traffic, water treatment facilities for clean and dirty water, ports and harbors, and power generation and distribution systems. This accounts for a vast range of structures manufactured from a relatively small number of materials.

The materials employed in the construction of the infrastructure are predominantly masonry, structural steel, and reinforced concrete with certain materials dominating particular periods of infrastructure development. For example in the United Kingdom, the big push in the water industry in the Victorian era has left a large legacy of predominantly masonry built facilities, whereas the boom in highway construction in the 1960s resulted in large numbers of reinforced concrete bridges and other highway structures.<sup>1</sup>

During the second half of the twentieth century, the increased use in reinforced concrete allowed

The commonest causes of degradation result from exposure to the environment, most notably UV radiation, water, and chloride ions. For marine structures, the chlorides are present in abundance in the surrounding environment. For nonmarine structures, the chlorides can come from deicing salts or admixtures in concrete. During winters, in much of Europe and North America, many hundreds of thousands of tons of rock salt is spread onto the road networks in an attempt to clear snow and ice. This is rarely followed up in the spring by any attempt to remove residual salt from the associated infrastructure, resulting in considerable chloride-related collateral damage in the following years.

Other branches of infrastructure have their own aggressive environments with which to deal. The water industry has to cope with a wide range of natural and artificial chemical environments. Freshwater can be acidic and soft, which can dissolve concrete and carbonaceous masonry and prevent the formation of calcareous scales upon which cast iron pipes rely for their corrosion protection. Anaerobic bacteria in sewage and other organic waste materials generate

hydrogen sulfide, which can be oxidized into sulfuric acid by aerobic bacteria. Hydrogen sulfide is incredibly aggressive to ferrous materials, while sulfuric acid will attack most materials, including concrete.<sup>2</sup>

### 4.39.3 Consequences of Failure

There is a common thread that links the majority of infrastructure. The consequences of failure of infrastructure are often too great to contemplate, and typically a large number of people and livelihoods are affected. The results of a failure can be marked and potentially life threatening. However, there is a general cozy assumption in most societies that bridges do not collapse, power stations will continue to operate come what may, and the water supply will always be safe and available. This idyllic view relies totally on the quality of the inspection and maintenance regimes adopted for the infrastructure.

The basic management approach is that repair requirements are identified primarily via routine inspection programs. However, the fundamental problem is that repair work is severely constrained by the fact that the infrastructure is generally subject to public funding. In addition to cost limitations, infrastructure, by its very definition, often cannot readily be taken off stream. For a major road, it can only be closed for maintenance if there is a suitable alternative route. As a consequence, works often have to be carried out at night, or using innovative access methods. All of this can have a significant impact on the cost of the works, such that access and traffic management can often cost more than the actual repair.

Politically, funding for the maintenance of infrastructure is often given a relatively low priority. Such works are seen as disruptive, and given the general public perception that infrastructure does not deteriorate and is essentially maintenance-free, it may prove attractive to delay such works until absolutely essential. As a result of this, maintenance is commonly underfunded and there is often a significant backlog of critical maintenance. For example, a recent study identified that between 30% and 60% of bridges in the United States are deficient as the result of corrosion aggravated by the lack of proper maintenance programs.<sup>3</sup>

The management of infrastructure spending is often complex and involves allocating limited resources in the most efficient manner. This will usually be linked to a program of inspection, which

feeds into a maintenance plan where works are prioritized. The development of effective inspection and reporting methods are, therefore, key to the operation of an effective infrastructure maintenance system. An example of such procedures is given later with respect to the inspection of highway bridges in the United Kingdom.<sup>4</sup>

### 4.39.4 Inspection Requirements

The basic procedure most commonly adopted is to use routine visual inspection by experienced personnel. This is an efficient method of gathering data but is aggravated by the nature of most infrastructure in being large and in near-constant use. Access for visual inspection may therefore be difficult and will often have to take advantage of temporary closures or offpeak working.

An additional factor is that most structures built more than 20 years ago did not necessarily consider the requirements for future inspection. In some cases, it was assumed that inspection would not be required. Structures were typically designed to prescriptive codes that were meant to ensure durability; however, material properties and safety factors and sometimes even exposure conditions changed over time. It was only when corrosion was being observed on a more widespread scale that it began to be considered as an issue, but even then the perception remained that if a structure was designed to the relevant code it will achieve the design life. The concept of design life is in fact not related to a period that a structure is expected to survive but rather a return period for a statistical loading regime, for example, a 1-in-100-year storm, or traffic loading.

As durability and future inspection was not considered to be an issue, access for such inspections was not incorporated into the design. The aim was to achieve a structure that was simple and cheap to construct. As a result, details are commonly encountered that are particularly vulnerable to deterioration, but all impossible to inspect.<sup>5</sup> A classic example in a bridge is the half joint as shown in [Figure 1](#).

Joints are required to allow for thermal movement and are sealed to prevent debris and water from penetrating to the substructure. However, the material used as a sealant is typically not sufficiently durable, and the action of traffic and thermal movements of the structure will ultimately result in leaks. The water, plus any deicing salts or other aggressive chemicals present

**Figure 1** Bridge half-joints.

on the road surface, penetrates the joint and pond on the bearing shelf below where the bearings, now sat in a solution of chlorides and hydrocarbons, start to corrode. Chloride-laden water may also be running down the columns supporting the deck, penetrating the concrete and initiating corrosion of the steel reinforcement. The deck itself will be supported by beams of either steel or reinforced concrete, neither of which will benefit from exposure to the salty, contaminated water running through the joints.

Ports and harbors have obvious limitations on visual inspection, as large parts of the structures can be immersed. For steel sheet piling, corrosion is normally addressed by employing a corrosion allowance in the form of additional thickness of steel for tidal and atmospherically exposed areas. For the permanently submerged areas, the lack of oxygen at depth can stifle corrosion, but the action of microbes in the environment can lead to a phenomenon known as accelerated low water corrosion (ALWC) where large section losses in excess of  $1 \text{ mm year}^{-1}$  can be found in the vicinity of the lowest astronomical tide. This is far in excess of the corrosion allowance, and coincides with the area of highest structural load and the least inspectable part.

Similar problems occur for underground transit systems. These are often constructed from cast iron or reinforced concrete segments bolted together to form a tunnel. There may be a hydrostatic pressure across the joints between segments and rings, and the water may be contaminated with chlorides, sulfates, and other aggressive species.

There is a wide range of equipment available for assisting experienced personnel in carrying out visual inspections, such as endoscopes and CCTV equipment. Together with improved access equipment, these make the inspection of infrastructure safer and more effective. **Figure 2** shows a hydraulic under-bridge unit in use on a bridge inspection.

#### 4.39.4.1 Inspection Methods

Besides any initial visual inspection, the inspection methods adopted may be destructive or essentially nondestructive. Commonly employed nondestructive tests for reinforced concrete that are able to assess structural integrity and remaining long-term performance are delamination tests, rebound hammer (compressive strength), covermeter survey, dust sampling, and half-cell surveys. Destructive concrete breakouts allow the inspection of the reinforcement and the determination of the depth of carbonation. The type and extent of the inspection usually depends on the initial visual observations.

Delamination tests can be carried out using a hammer to identify areas where cover concrete has spalled due to the expansive reaction of reinforcement corrosion. The formation of the more voluminous steel corrosion products, that is, the rust, results in the delamination of the cover concrete caused by induced stress exceeding the concrete tensile strength.

The depth of carbonation, a natural process by which carbon dioxide in the air forms carbonic acid which neutralizes the alkalinity, can be established by

**Figure 2** Underbridge unit. Photo courtesy of Wemo-Tec GmbH.

applying phenolphthalein indicator to a freshly broken section of concrete. The change from colorless to purple indicates that the pH of this area is above 9, which in turn demonstrates that any steel reinforcement in the concrete should be protected from corrosion by the alkaline environment. Colorless areas show the concrete to be carbonated and the reinforcement to be at risk of corrosion. It should be noted that reinforcement can still corrode in an alkaline environment in the presence of chloride ion contamination.

The bar size and cover depth of reinforcement can be identified by means of a covermeter which generally use electromagnetic or eddy current techniques to locate the steel. [Figure 3](#) shows an electromagnetic covermeter being used to locate prestressing tendons in precast concrete beams. Their use is limited to certain depths, which may be affected by the presence of a screed. Where the absolute size, depth, and condition of reinforcement need to be identified for the purposes of structural assessment, covermeter readings should be used in conjunction with destructive breakouts.

To determine the risk or occurrence of reinforcement corrosion, the structure can be tested with respect to chloride ion content and electrochemical activity of the steel within the concrete. The chloride content is usually determined from concrete dust

samples obtained from different depths using a percussion drill.

The immediate surface is discarded, as it is likely to contain contaminants that are not representative of the bulk of the concrete. Incremental samples are then taken at depths that typically represent the cover, the environment adjacent to the steel, and the concrete beneath.

Half-cell potential surveys are a rapid method of establishing any corrosion ‘hotspots’ within key reinforced concrete elements. These may be defined as areas where corrosion of the reinforcement is likely to be occurring and differs in electrical potential from an adjacent area by more than 100 mV. There is considerable guidance on the use of this and other associated electrochemical techniques, and they provide a useful method of scanning large areas and identifying locations for other testing.<sup>6</sup> A typical output of a half-cell potential survey at 0.25 m centers where the red areas indicate highest corrosion risk is shown in [Figure 4](#).

The Schmidt Hammer or rebound sclerometer test is a simple and quick nondestructive method to obtain an estimate of the compressive strength of concrete. It is a device that impacts a concrete surface with a sliding mass at a given energy as generated by a spring under a preset compression. The rebound of the sliding mass or hammer is governed by the hardness of the concrete

**Figure 3** Electromagnetic covermeter used to locate steel reinforcement.

**Figure 4** Typical results of a half-cell potential survey at 0.25 m centers, where the red areas indicate highest corrosion risk.

structure. As there is a relationship between hardness and compressive strength, the values obtained from the Schmidt Hammer can be converted into strengths for the area of concrete tested. The test should be carried

out in accordance with relevant standards.<sup>7</sup> The results should be considered as an estimation of the actual strength and verified with conventional strength tests on cubes or cores taken from the structure.<sup>8</sup>

#### 4.39.4.2 Remote Monitoring

There is a considerable range of embeddable probes currently available that can be employed to detect the onset and development of corrosion in large structures.<sup>9</sup> Such probes work best when installed at the time of construction, but in many cases, they are required to be retrofitted to existing structures wherein some degree of corrosion or other degradative process may already have occurred.

Selecting areas for the inclusion of probes is not without its problems. It is often relatively simple to identify the areas most likely to suffer from corrosion, such as under a joint, or elements where corrosion would constitute a significant risk, such as post-tensioned tendons. A specific length of motorway may have many thousands of potentially vulnerable areas, some of which will fail, while the majority will not. The chlorides from deicing salts will leak on to the substructure and then spread over the surface of the concrete and penetrate into the steel. A specific area, possibly less than a few square centimeters, may then start to corrode. The precise location of probes is therefore always going to be difficult as there is a significant chance that corrosion may be missed unless a large number of probes are employed in combination with regular visual inspections and other complementary monitoring techniques. Considerable effort is being directed towards the development of more effective monitoring systems that can assist in the long-term maintenance of complex infrastructure systems.<sup>10</sup>

#### 4.39.4.3 Structural Considerations

The wide variety and complexity of infrastructure encompass a wide spectrum of loading requirements. For example, in pipelines the loading is relatively uniform and so areas of greatest concern are those areas where corrosion is most likely to occur and such areas therefore may be targeted for risk-based inspections. For liquid retaining structures, the load increases with depth and so at the design stage the structural capacity will increase with depth to accommodate this. For bridges, the loading similarly varies across each element and so the design will also vary to accommodate the necessary structural properties. As a consequence, for any given amount of corrosion each area will be affected to a different degree. A loss of 2 mm of steel thickness may not be considered significant in one location, but may be critical in another and, whereas a structural member may be

able to tolerate the full loss of section in some areas, a pipeline cannot be allowed to form even the smallest perforation. As a result, the inspection cannot simply focus on areas of highest corrosion but must review the whole structure.

This is further aggravated by changes in the design approach adopted by the relevant statutory or advisory bodies. Over a period of time, the approach to the specific design requirements often changes as other factors become more significant. The purpose of parapets, for example, initially used to be essentially to form an edge to a structure. They are now required to provide effective vehicle restraint to faster and heavier impacts. The predicted loading has changed from simply being able to support the self weight and survive wind loading, to restraining a vehicle impact at 50 kph. Changes in the guidance and requirements mean that many structures will fail to achieve the standards laid down by the design codes. It can be tempting to adopt the approach of 'it has not yet fallen down,' but then all unexpected collapses are preceded by a prolonged period of inactivity, and hence the requirements for well-defined and carefully managed inspection regimes.

#### 4.39.5 Highway Infrastructure

The 1980 Highways Act<sup>11</sup> established a statutory obligation to maintain public highways in the United Kingdom. However, the responsibility and procedures to be employed in this maintenance depended on the ownership of the structure. The primary routes are maintained by the Highways Agency, which is an executive agency of the Department of Transport. The remaining bridges fall under the responsibility of a wide variety of parties, such as local authorities, the railway and canal network, and other utilities where their structures pass over the highway.

The absence of a common code of practice has led to a range of different approaches being taken, which was less than desirable. To help clarify this situation, a document entitled 'The Management of Highway Structures' was published in 2005.<sup>12</sup> Its stated aims were "... to encourage and assist highway authorities and other owners to implement Good Management Practice, harmonise practices, coordinate approaches and share their experiences and practices." Three key themes were identified, these being asset management planning and resource accounting, maintenance planning and management, and engineering processes.

Asset management may be defined as a strategic approach that identifies the optimal allocation of resources for the management, operation, preservation, and enhancement of the highway infrastructure to meet the needs of current and future customers. The asset management plan is a long-term view. Maintenance planning and management involves the development and implementation of cost-effective maintenance plans for highway structures that support the safe operation of the network while delivering the required levels of service. The maintenance plans typically cover both short- and medium-term actions and requirements.

The engineering processes are the necessary practical measures and data collection exercises. These include inspections to identify the current condition, assessments to identify the current capacity, and the approach to be taken to manage abnormal loads. These themes are supported by data and information, which are normally stored within a computerized bridge management system. This enables the data to be interrogated and manipulated to provide useful information on the structures and network.

Central to all of this is the inspection procedure. It is not possible to accurately assess a future maintenance requirement unless the existing condition is known. In order to achieve this, the code of practice proposes the following series of inspections, all of which are carried out by appropriately skilled and competent professionals.

1. General inspections (GI) are required every 2 years. They are primarily visual inspections carried out from readily accessible areas. As such, it is not expected that these will provide a comprehensive and detailed view of each part of the structure.
2. Principal inspections (PI) are carried out every 6 years, and the intention is that they are carried out within touching distance of all elements, unless suitable alternatives can be justified, for example, remote CCTV inspection of areas with difficult access.
3. Special inspections (SI) are carried out as and when deemed necessary. They can include inspections required as part of the assessment process. They can also include inspections carried out under the grounds of public safety, or inspections relating to acceptance of repair work or at a hand-over stage where maintenance responsibility is being transferred.

The Management of Highway Structures contains 17 recommendations, which, it states, should be

implemented in a measured way. Three milestones are proposed.

1. Milestone 1 covers the adoption of processes necessary to provide highway structures that are safe to use, inspect, and maintain.
2. Milestone 2 adds the broad inclusion of additional processes necessary to provide highway structures that are fit for purpose and meet government requirements.
3. Milestone 3 imposes the adoption of processes necessary to deliver the agreed level of services at minimum whole-life costs and represents the full implementation of the good management practice set out in the code. It is stated that ideally the milestones should be implemented in order, but it is considered appropriate to progress to some actions in Milestone 3 before Milestone 2 is fully achieved.

The German standard for bridge monitoring and inspection states that GI of easily accessible areas should be carried out every 3 years and PI of the entire structure every 6 years.<sup>13</sup> SI should be carried out after certain events have occurred, such as flooding, hurricane, and accidents. The standard notes that all structural components such as protectively enclosed elements are to be inspected. The standard is based on a guidance from 1930 which dealt with the monitoring and inspection of cast iron highway bridges.

In Italy, an equivalent standard covers the inspection of highway structures.<sup>14</sup> It recommends that an inspection of those elements of the bridge visible from accessible areas should be systematically carried out. The aim of this inspection is to identify all the possible signs of deterioration such as cracking, superficial deterioration, moisture staining, exposure of steel bars, difference in color of concrete surfaces, and structural deformation. Depending on the result of this first inspection and on the structural characteristics and importance of the bridge, a more detailed inspection should be planned. The detailed inspection should be carried out at touching distance on all the elements of the structure including the foundations and the embankments.

Similar guidance is available in all countries with a significant highway-based infrastructure.

#### **4.39.6 Other Infrastructure**

Multiple storey car parking structures have featured in a number of high-profile failures in recent years.

The traditional approach of managing car parks has typically been to carry out the minimum level of maintenance possible, and owners, often private companies, have appeared unaware of the consequences of degradation. Innovative designs and rapid construction methods coupled with poor construction practices have often exasperated the problems. Many date from the early 1970s when the designs often did not include for a degree of robustness. This, combined with a lack of understanding of the corrosion processes, has resulted in many corroding structures with low factors of safety and an increased risk of failure or collapse. **Figure 5** shows the typical appearance of such structures with patching of the damaged areas.

Following on from the collapses, guidance documents were produced in the United Kingdom with regard to the design, maintenance, and refurbishment of multistorey car parks.<sup>15</sup> The guidance followed similar lines to those contained within the bridge management code of practice, namely that the current condition and load-carrying capacity should first be established and a more active inspection and maintenance regime be implemented. This included benchmarking using appropriately qualified and competent personnel to establish the current condition. In addition, routine inspections were recommended by on-site staff to identify areas such as

blocked drainage which would produce future durability issues.

The majority of other maintainers in the United Kingdom and elsewhere are generally private companies. These tend to be left to carry out their own procedures, although obviously any major incidents would be investigated. Shortfalls that result in the health and safety of employees or the public being put at risk or those that adversely affect the environment would be expected to result in criminal prosecutions under the relevant statutes.

Street lighting and signage is another area that at first glance would not appear to be a significant problem other than periodic maintenance of the luminaires. However, the lights and signs are typically fixed at height to large posts which are generally fabricated from metal or reinforced concrete and therefore subject to corrosion in aggressive environments, as well as suffering occasional unreported impact damage.

Inspection of the posts for internal and external corrosion is not in itself particularly onerous or technically challenging. It is the sheer number of units requiring inspection that lead to concerns. Kent County Council in the United Kingdom with an area of 3736 km<sup>2</sup> and a population of 1.6 million reports having a total of 113 000 street lights, 14 000 lighted signs, and 5500 bollards. Extrapolated to the

**Figure 5** Multiple patch repairs to car park deck.

whole country, this would equate to something in excess of 4 million lighting and signage posts requiring periodic inspection and maintenance. With such large numbers to deal with, the occasionally reported failures must represent a very small percentage of the whole.

#### 4.40.1 Industry Scope

Petrochemicals and chemicals manufacture comprises a major sector of most developed and developing economies. The primary feed-stocks are oil, gas, and naturally occurring materials that are processed in large quantities in world scale plants to produce refined oil products and commodity chemicals. Downstream processing is undertaken in progressively smaller plants to produce the wide range of complex chemical products that are demanded by developed economies. Value is added through each stage of processing so that at the end of the chain, fine chemicals and pharmaceuticals, although manufactured in relatively small quantities, are very significant economically because of their high intrinsic value.

The industry is driven by the usual commercial imperatives. It strives to create value through new and improved products and processes, increased energy and resource efficiency, and improved manufacturing performance. At the same time, the industry is acutely aware of its societal obligations to comply with safety, health, and environmental (SHE) expectations and regulations that preclude loss of containment incidents.

#### 4.40.2 Risks to Industry Equipment

Process plants, typified in [Figure 1](#), are assembled from standard equipment items that are subdivided conventionally as follows:

1. storage tanks;
2. pressure vessels – reactors, heat exchangers, columns for distillation/fractionation/stripping, storage spheres/tanks, etc.;

Industry scope:

- Petroleum refining
- Petrochemicals
- Commodity chemicals
- Fine chemicals
- Pharmaceuticals

Equipment

- Storage tanks
- Pressure vessels
- Fired equipment
- Machines
- Piping
- Instrumentation

**Figure 1** Process plants, regardless of size/complexity, are assembled from standard equipment items.

3. fired equipment – furnaces, heaters, boilers, etc.;
4. machines – gas/steam turbines, compressors, expanders, pumps, etc.;
5. piping – including valves, venturi tubes, orifice plates, etc.;
6. instrumentation – measuring temperature, pressure, concentration, flow, etc.;

Industry equipment operates over wide ranges of temperature and pressure as well as in a wide range of corrosive environments. Operating conditions for some common items of industry equipment are summarized in [Figure 2](#). Thus, liquefied hydrocarbons are stored at atmospheric pressure at extremely low, subzero temperatures, while furnace tubes may operate at significant pressures at temperatures around 1000 °C. Crude oil is distilled at atmospheric pressure, or even under vacuum, while hydrocrackers and ammonia/methanol converters operate at pressures in the range 200–300 bar at temperatures that can be well above 400 °C. Some processes for the manufacture of low-density polyethylene (LDPE) operate at pressures as high as 3000 bar.

At the extremes, the temperatures and pressures at which industry equipment is required to operate present significant challenges to the properties of available engineering materials. Design codes for industry equipment provide protection against mechanical failure due to ductile overload, brittle fracture, fatigue and creep mechanisms. However, industry equipment is also vulnerable to failure modes associated with the full range of corrosion and/or wear mechanisms during operation, and design codes offer only very general guidance as to the mitigation of such risks in specific applications.

Historically, piping and storages have proved the likeliest types of equipment to give rise to major incidents,<sup>1</sup> as recorded in [Figure 3](#). This is to some

**Figure 2** Operating conditions for common items of petrochemical/chemical industry equipment.

extent counterintuitive and is probably a reflection of their lower historical priorities in the management of structural integrity compared to more obviously vulnerable equipment types such as pressure vessels or machines. Regarding mechanisms of failure, periodic surveys have confirmed that cracking, in particular environmentally assisted cracking (EAC), and general corrosion are the commonest causes of equipment failure in the industry as, for example, in a recent survey of the refining/petrochemical industry in Japan<sup>2</sup> from which **Figure 4** is adapted.

These corrosion risks have to be managed to preclude major incidents and eliminate avoidable costs. A number of sources provide comprehensive

overviews of the mitigation of corrosion risks in the process industries.<sup>3–8</sup> The challenge is to select materials, protection procedures, and fabrication procedures for equipment that enables value creation while containing SHE risks within acceptable limits. Corrosion management is a life cycle process, the available tools for which are:

1. At the equipment design stage, selecting corrosion-resistant materials and protection practices and adopting good design practices for equipment that mitigate corrosion risks.
2. Throughout the operating life, dimensioning and understanding the corrosion performance of

**Figure 3** Types of process equipment involved in 170 major industry losses over 30-year period. Adapted from Garrison, W. G. *Hydrocarb. Process.* **1988**, 67, 115–122.

equipment and managing corrosion control practices to assure structural integrity and provide increased reliability and availability.

3. At all stages, promoting awareness and commitment among engineers and managers.

### 4.40.3 Materials and Protection Practices for Process Equipment

#### 4.40.3.1 Materials

Most classes of materials find use in process industry equipment because of the wide ranges of temperatures, pressures, and corrosive environments that have to be tolerated. The approximate capabilities of the more important classes of material as a function of temperature are charted in **Figure 5**. The needs of the process industries for equipment to withstand ever more demanding conditions have provided significant drivers for the development of new and improved grades of engineering materials across all classes that are too numerous to mention here but are described in detail in this book in the relevant chapters on materials.

The strength and ductility required for the safe operation of pressurized equipment are confined mostly to metallic materials, although some lower-pressure/temperature systems are constructed in thermoplastic and fiber reinforced plastic (FRP)

materials. Carbon and carbon–manganese steels are workhorse materials for process equipment because of their low relative cost, but they have limited strength and ductility at high and low temperatures respectively, as well as poor corrosion resistances. A number of low-alloy steels also find significant usages:

1. Chromium–molybdenum–vanadium steels provide improved strengths at the temperatures that are required for handling environments such as steam and that occurring in hydroprocessing. They also provide increased resistance to hydrogen-containing gases at elevated temperatures.
2. Chromium steels provide improved resistance to high temperature corrosion, particularly in gases containing hydrogen sulfide.
3. Nickel steels provide improved ductility for low-temperature duties, in particular for the storage of liquefied gases and hydrocarbons.

Higher-strength medium- or high-carbon grades of steel generally lack the ductility for pressure containment duties but find uses in machines as materials for shafts, gears, punches, extrusion dies, cutting tools, etc.

The austenitic and duplex stainless steels and nickel alloys provide acceptable strengths and ductility over much wider temperature ranges than steels as well as much greater corrosion resistance, and they are widely used for process equipment.

**Figure 5** Approximate temperature capabilities of materials in process equipment.

Specific grades have been developed to address specific corrosion risks in the process industries such as resistance to stress corrosion cracking and pitting/crevice corrosion, reducing and oxidizing acid corrosion and specific high temperature corrosion phenomena. Ferritic, martensitic, and precipitation hardening stainless steels also have useful corrosion resistance but have weldability and potential ductility issues that constrain their use for pressure containment. Ferritic stainless steels find most uses in relatively thin section components such as heat exchanger tubing. Martensitic and precipitation hardening stainless steels find uses where stronger materials are required such as shafts, impellers, valve springs, bolting, etc.

The other alloy classes find niche uses in process equipment:

1. Titanium, zirconium, and tantalum alloys have excellent corrosion resistance, but their applications are constrained by their relatively high cost and limited strength at higher temperatures that are offset to some extent by deploying them as linings on steel substrates.
2. Aluminum alloys have restricted corrosion resistance and are mostly confined to relatively noncorrosive applications such as storage tanks and silos.
3. Copper alloys find niche applications arising from their corrosion resistance in relatively low-temperature applications including heat exchanger tubing and tube plates, and pumps and valves.
4. Cobalt alloys are used mostly for their excellent resistance to wear in equipment that handles solids and slurries.
5. Lead alloys find continuing but declining uses as lining materials for tanks and vessels handling principally sulfuric and phosphoric acids.

Nonmetallic materials find important and increasing usage in process equipment, some of which are illustrated in [Figures 6 and 7](#). Refractory linings are deployed routinely as thermal protection for steels, allowing them to operate at the temperature ranges within which they have adequate strength for pressure containment. For corrosion resistance, chemically resistant brick and glass linings have also found significant application. In general, solid engineering ceramics lack the ductility to deploy directly for pressure containment. However, they are highly corrosion resistant and find increasing usage as internal components of equipment for corrosive duties as illustrated in [Figure 6](#). These applications include heat exchange duties in the cases of impervious graphite and silicon carbide that are thermally conducting.

**Figure 6** Process equipment internal components constructed in engineering ceramics: (a) partially stabilized zirconia valve components,<sup>9</sup> (b) silicon carbide heat exchanger tubing,<sup>10</sup> (c) impervious graphite bubble cap tray,<sup>11</sup> (d) acid-resistant brick-lined vessel.<sup>12</sup>

**Figure 7** Process equipment items constructed in plastics (a) 60 cm diameter polypropylene piping. Reproduced from [www.ianflockton.co.uk](http://www.ianflockton.co.uk) (b) ~1000 m<sup>3</sup> PVDF-lined GRP vessel. Reproduced from [www.chemicalprocessing.com](http://www.chemicalprocessing.com)

Thermoplastic and FRP materials have also found significant and increasing usage in process equipment because of their wide ranging corrosion resistance. Some of the more common materials (polyethylene (PE), polypropylene (PP) and polyvinyl chloride (PVC)) compete favorably with steel on cost. In the case of the higher-performance thermoplastic materials such as the fluoropolymers (PVDF, FEP, PTFE) and polyetheretherketone (PEEK), useful properties persist up to relatively high temperatures, albeit at a cost. There are available design codes for solid thermoplastic and FRP tanks, vessels, and piping systems. Allowable combinations of pressure and size are constrained by the relatively low strengths and temperature tolerances of the relevant materials, but at low temperatures and pressures, relatively large fabrications are achievable as illustrated in **Figure 7**. Pressure and size restrictions are overcome to some extent by deploying the materials as coatings and linings on stronger, tougher substrates. Thermoplastic linings can be used on FRP substrates in so-called dual laminate constructions. Alternatively, thermoplastic, FRP and elastomeric linings are used on steel substrates. Elastomers also have essential uses in sealing materials.

#### 4.40.3.2 Protection Practices

##### 4.40.3.2.1 Coatings and linings

Thin paint coatings, generally <0.5 mm thick, are used routinely for the protection of structural steelwork and external surfaces of steel equipment against atmospheric corrosion and also find uses for the internal protection of process equipment.<sup>13</sup> Thicker coating systems up to ~2 mm<sup>14</sup> are available for the internal protection of storage tanks, vessels, and pipelines based

on heat-cured fluoropolymer and other resin systems that may be reinforced with wire mesh and antipermeation layers for particularly corrosive duties.

Metallic coatings also find uses. Dipped zinc and zinc/aluminum coatings are commonly used for the protection of structural steelwork in chemical plants, but their use on equipment surfaces is constrained by any attendant risks of liquid metal embrittlement (LME). Thermal spray coatings of, for example, aluminum or stainless steels sealed with organic materials are sometimes used for repair and protection against relatively low corrosion rates. Thermal spraying is also used to apply a wide range of erosion-resistant coatings, including nickel- and cobalt-based alloys, sometimes incorporating hard materials such as carbides.

Relatively thin coatings are more likely to contain defects than thicker linings which are generally favored as the more prudent option for protection where substrate corrosion rates are likely to exceed ~0.5 mm year<sup>-1</sup>. Linings are used where the cost and/or mechanical properties of the corrosion-resistant material preclude its use in solid form. Metallic linings are applied by one of the following processes:

1. Roll bonding; routine for stainless steels and nickel alloys on steel, typically 1.5–5 mm thick.
2. Explosive bonding; especially for metals that cannot be fusion bonded to steel such as titanium, zirconium, and tantalum, 3–25 mm thick.
3. Weld overlaying; mainly stainless steels, nickel alloys, and hard surfacing alloys, up to 25 mm thick.
4. Wallpapering; in which thin sheets, typically 1.5 mm thick, are welded intermittently to substrates and sealed with overlaps that are welded continuously,

for stainless steels and nickel alloys on large areas such as ducts.

5. Loose lining; for expensive materials such as tantalum, typically 0.5 mm thick.

Thermoplastic, FRP and elastomer linings, up to ~5 mm thick, are preferably bonded to the substrate, usually steel, but in some applications rely on mechanical bonding such as in the case of swaged thermoplastic linings in steel pipes. Bonded glass linings up to ~2 mm thick and much thicker brick linings continue to find significant uses.

#### 4.40.3.2.2 Inhibitors

The principal uses of inhibition in chemical plant is in the control of corrosion in steam raising and cooling water systems that are covered in separate chapters in this book. However, inhibition finds niche uses in the control of process corrosion, such as in the control of crude unit overhead corrosion<sup>15</sup> and the control of corrosion in CO<sub>2</sub> removal systems.

#### 4.40.3.2.3 Electrochemical protection

Cathodic and anodic protection are described in separate chapters in this book. Cathodic protection finds conventional uses for the control of external corrosion of immersed and buried steel infrastructure and pipelines. Anodic protection is based on the development and/or consolidation of protective films on steel and stainless steel equipment to control corrosion at acceptable rates and prevent unacceptable contamination of process fluids with corrosion products. The main commercial applications of anodic protection are in sulfuric acid storage tanks, piping and coolers and in pulp digesters and storage tanks handling caustic kraft liquors in the pulp and paper industry.

#### 4.40.3.3 Selection of Materials and Protection Practices for Process Equipment

The procedures that are used to select materials and protection practices and to factor costs into the selection process are described in separate chapters in this book. One of the more important requirements is that the level of risk inherent in the outcome is understood and aligned to the overall philosophy for managing technical and commercial risks in the specific application. The extent to which such risks need to be quantified rigorously depends upon the application and, in particular, the consequences of corrosion failure.

In the process industries, the SHE risks inherent in the selection of materials and protection practices are embedded in the hazard study methodologies<sup>16</sup> that are deployed throughout process and equipment design at its various stages. Such methodologies attempt to ensure that the risks are contained within the acceptable, defined limit values. Risks, including those arising from the selection of materials and protection practices, are evaluated and mitigated by teams of functional professionals, including materials/corrosion engineers.

In the process industries, the semiquantitative evaluation of corrosion risks is normally regarded as sufficient, based on the essentially empirical corrosion data that is used to predict corrosion performance, the reliability of which is normally classified as of high, medium or low reliability, depending on the source. For example, the American Petroleum Institute classifies the reliability of corrosion data as follows<sup>17</sup>:

1. High-reliability sources – extensive field data through inspection, test coupon data from >5 years' exposure in operating equipment.
2. Moderate reliability sources – laboratory testing with simulated process conditions, limited operating plant corrosion coupon testing.
3. Low-reliability sources – published data, corrosion rate tables.

It is vital that the selection of materials and protection practices are documented to capture the know-how that they embody, record any changes that are required and render the information accessible to the wider community of engineers and managers concerned with the design and operation of process equipment. The use of materials selection diagrams (MSDs) is being adopted increasingly for these purposes.<sup>18</sup> MSDs comprise simplified process flow diagrams showing relevant operating conditions together with materials selection information and any associated corrosion protection practices. These diagrams capture the information needed to ensure that materials selection decisions for the many specific items of equipment that comprise the final plant (vessels, piping, machines, instrumentation) incorporate the outcomes of corrosion-risk identification and evaluation, together with any necessary mitigation practices, for the relevant operating conditions. This is particularly important to mitigate the risks of deficient information transfer across organizational boundaries when materials selection decisions are spread across several supplier organizations.

#### 4.40.4 Mitigation of Corrosion Risks by Good Detailed Design, Procurement, and Construction Practices

The extent to which detailed design may have a significant influence on corrosion risk and its mitigation is covered in a separate chapter in this book that includes many examples of bad and good practices relating to the design of process equipment, particularly in relation to environmental, thermomechanical, geographic or geometric, and galvanic compatibility factors. Probably, the greatest corrosion risk to process equipment at the design stage arises from the difficulties in anticipating and defining the development of aggressive local chemistries under the following influences:

1. Concentration by repeated wetting/drying cycles on hot surfaces under thermal insulation, on heat transfer surfaces, and at wind and water lines.
2. Concentration in crevices and beneath scales/deposits.
3. Condensation onto surfaces below critical dew points.

Examples of the first two risks and their mitigation in relation to the design of heat exchangers are given in this book in the chapter on design. An example of condensation-induced risk is summarized in [Figure 8](#) which shows a section through the bottom of a steam reformer tube where the tube is welded to a branch on a refractory-lined header beneath a

furnace base. The tube has cracked along the fusion line between a nickel alloy weld joining the low-alloy steel header branch to the cast stainless steel reformer tube, resulting in leakage of process gas. The cause of the problem is that the section of tube around and below the dissimilar weld behind some insulating refractory operates intermittently below the dew point of the process gas that is nominally  $\sim 160^\circ\text{C}$ . The condensate is acidic because of its  $\text{CO}_2$  content resulting in corrosion of the low-alloy steel branch bore, and environmentally assisted cracking of hard material that is formed during welding along the fusion line between the nickel-alloy weld and the low-alloy steel branch. The root cause of the problem lies in the design that allows a damaging microenvironment to develop around a dissimilar metal weld as a result of repeated condensation/dry out events. The risk is mitigated by changing it to a 'hot bottom' design for the reforming furnace in which the temperature of the dissimilar metal weld is maintained permanently above the dew point of the process gas.

During the procurement and construction stages, additional corrosion risks may be incurred if the correct materials and protection practices are not procured or deployed according to specification. An example of the very expensive consequences of failure to implement correctly a specified corrosion-risk mitigation practice is shown in [Figure 9](#) that relates to an economizer on a nitric acid plant. The vertical, tubular

**Figure 8** Environmental cracking of a dissimilar weld attaching a reformer tube to a header resulting from intermittent condensation of the process gas, dew point  $\sim 160^\circ\text{C}$ , behind insulating refractory.

**Figure 9** Nitrate stress corrosion cracking of steel tube plate of a nitric acid plant economizer during plant startup because of poor thermal stress relief during fabrication.

heat exchanger is used to preheat boiler water with the hot, gaseous products of ammonia oxidation. Such vessels are routinely constructed in carbon steel and are operated sufficiently hot in service to preclude condensation of nitric acid that would result in severe corrosion. However, during startup there are significant amounts of unreacted ammonia present in the process gas and condensation of ammonium nitrate solution can occur on the relatively cool bottom tubeplate, presenting a risk of nitrate stress corrosion cracking to stressed carbon steel. The risk was mitigated by revising the stress relieving procedure in collaboration with the fabricator to ensure that the vessel be thermally stress relieved as a last stage of fabrication. In the case of the failure summarized in [Figure 9](#), the vessel was inadequately stress relieved and, as result, suffered such rapid nitrate stress corrosion cracking that the bottom tube plate leaked during the startup procedure. The risk was mitigated by reviewing the stress-relieving procedure with fabricator to ensure that residual stresses were reduced below the SCC threshold.

#### 4.40.5 Mitigation of Specific Corrosion Risks

##### 4.40.5.1 External Corrosion Risks

Carbon steel and reinforced concrete infrastructure such as structural steelwork and pipe bridges is

vulnerable to atmospheric corrosion in chemical plants that may be exacerbated by contamination of the atmosphere by process fumes and/or fluids and is mitigated by the use of appropriate coatings. More insidious corrosion risks arise on carbon and low-alloy and stainless steel equipment surfaces beneath fireproofing and thermal insulation materials. Passive fireproofing materials are based normally on Portland cement or lightweight concretes (e.g., vermiculite). The most commonly used thermal insulation materials are organic foams such as polyisocyanurate (PIR) foam, mineral wool and calcium silicate that are preferred for cold (below ambient), warm (typically  $< \sim 350^\circ\text{C}$ ) and hot (typically  $> \sim 350^\circ\text{C}$ ) duties, respectively. The insulation is normally overlaid with mastic or clad with metal to prevent water ingress.

Corrosion risks arise when water from rainfall, cooling tower spray, leakage or spillage, fire deluge systems or other sources penetrates through cracks in the fireproofing or gaps in the outer insulation system arising from the loss of weatherproofing because of poor design and/or construction, deteriorated seals or mechanical damage. Corrosion risks are increased if water is entrapped on horizontal surfaces without drainage or in the annular spaces between equipment surfaces and deteriorated protective coatings, thermal insulation or fireproofing. The corrosivity of the entrapped water depends on the composition of the fireproofing or insulation material. Portland cement

and calcium silicate produce relatively alkaline solutions that are least aggressive. Mineral wool produces relatively neutral solutions but organic foams can produce relatively acid extracts that are particularly aggressive. The corrosivity is further increased by acid fumes and accumulations of chlorides from coastal atmospheres, road salt and other sources which are further concentrated on hot equipment surfaces by repeated wetting/drying cycles.

Carbon and low alloy steels are vulnerable to general corrosion in the temperature range  $-5$  to  $\sim 150^{\circ}\text{C}$ . Below  $-5^{\circ}\text{C}$ , corrosion rates are very low and above  $\sim 150^{\circ}\text{C}$  surfaces are dry, although thermal cycling across the boundary temperatures can reintroduce corrosion risks. Corrosion rates peak in the temperature range  $80$ – $100^{\circ}\text{C}$  within which corrosion rates up to  $\sim 5\text{ mm year}^{-1}$  have been recorded. Particularly, vulnerable design features include penetrations of the insulation cladding at vents, drains, hangers, supports, valves, ladders, platforms and similar features, steam-traced systems, stiffening or insulation support rings and other water trap features and improper sealing at flange terminations, or hardened, cracked, or separated sealants. A classic example of corrosion of a warm vessel shell that experienced sustained exposure to water held up in a non-draining stiffening ring is shown in **Figure 10(a)**. Austenitic stainless steels under thermal insulation in the temperature range  $\sim 50$ – $150^{\circ}\text{C}$  are significantly vulnerable to external, chloride-induced, stress corrosion cracking (ESCC). Above  $\sim 150^{\circ}\text{C}$ , the risk is negligible because surfaces are dry although periodic cycling to lower temperatures reintroduces the risk. Below  $\sim 50^{\circ}\text{C}$ , the initiation and propagation of stress corrosion cracks are possible, depending on the hygroscopicity of the salts that are present, but operating experience confirms that the practical risks are very small for most process applications. A typical example

of ESCC of an austenitic stainless steel pipeline from which the insulation has been removed is shown in **Figure 10(b)**.

In a recent study of the costs of corrosion to the UK chemicals and petrochemicals sector,<sup>19</sup> external corrosion emerged as the largest individual source of expenditure on corrosion in the industry. This is, in large measure, a legacy cost associated with the remediation of elderly assets that were designed and constructed to standards that are now recognized as deficient in relation to the mitigation of external corrosion risks. The industry has devoted considerable effort to the mitigation of external corrosion risks and the resulting guidance has been codified.<sup>20–22</sup> For new equipment, the options are

1. Design of equipment to prevent water ingress by shedding water away from joints that are sealed effectively, and to prevent water hold-up by the provision of effective drainage.
2. Application of coatings that may be organic, if compatible with the service temperature range, or metallic; particularly, thermally sprayed aluminum (TSA) coatings and aluminum foil<sup>23</sup> have been identified as cost-effective for carbon and stainless steels, respectively.
3. Selection of corrosion-resistant materials for equipment; for small pipe sizes, austenitic stainless steel is an economic alternative to protected carbon steel for service temperatures below  $\sim 50^{\circ}\text{C}$ , and for equipment that operates at temperatures in the vulnerable range for ESCC, duplex grades of stainless steel may be an economic alternative to protected austenitic stainless steel.
4. Control of insulation composition, principally by the avoidance of PIR foam for warm insulation systems; inhibited insulation materials with controlled chloride levels are available but are not widely used.
5. Construction supervision, in particular the technical supervision and inspection of coating, fire-proofing, and insulation operations to ensure compliance with specifications.

For existing equipment, risks are mitigated by appropriate inspection and repair or replacement. Risk-based inspection (RBI) methodologies may be used to identify high-risk locations<sup>24</sup> that are examined after local insulation removal using surface crack detection and/or ultrasonic thickness measurement. There are available NDE techniques that do not require insulation removal, such as infrared thermography to detect areas of inadequate insulation,

**Figure 10** External corrosion under thermal insulation (a) general corrosion of carbon steel vessel shell and (b) external stress corrosion cracking of austenitic stainless steel pipe.

flash (profile) radiography to detect wall thinning of carbon steel pipework or small vessels and long-range, low-frequency ultrasonics to detect wall thinning of carbon steel pipework.

#### 4.40.5.2 Internal Corrosion Risks

Industry equipment is required to operate in a plethora of chemical environments that consist of or contain mixtures of organic chemicals and acids, mineral acids, alkalis, salts and gases. The recognition and mitigation of the attendant corrosion risks presents significant challenges but is enabled by the major progress that has been made in understanding and dimensioning the corrosion performance of engineering materials and good corrosion control practices in industry equipment. This work has inevitably focused on specific chemicals or common process fluids or operations that present significant SHE or financial risks in the event of failure due to corrosion during storage and/or processing. Much of this learning has been codified in the standards, and recommended practices of technical organizations that industry professionals use for collaborative work and guidance is available on the mitigation of corrosion risks arising from the major recognized corrosive environments including:

1. organic chemicals<sup>38,53</sup> and acids<sup>26,45</sup>;
2. mineral acids including sulfuric,<sup>25,41,43,54,55</sup> hydrochloric,<sup>27,33,46</sup> hydrofluoric,<sup>28,47</sup> nitric,<sup>29,33,44</sup> phosphoric,<sup>31,34,51</sup> carbonic<sup>35</sup> and mixed acids<sup>32</sup>;
3. alkalis including sodium,<sup>30,32,49</sup> potassium,<sup>39</sup> and ammonium<sup>30,39,49</sup> hydroxides;
4. salts, including chlorides,<sup>37,42</sup> hypochlorites,<sup>34</sup> sulfates,<sup>40</sup> and mixed salts<sup>52</sup>;
5. gases, including hydrogen chloride,<sup>27,46</sup> hydrogen fluoride,<sup>28,47</sup> chlorine,<sup>48</sup> ammonia,<sup>30,39,50</sup> hydrogen,<sup>56</sup> and hydrogen sulfide<sup>57</sup>;
6. specific process fluids or operations in the petroleum refining sector such as crude unit over-heads,<sup>15</sup> naphthenic acids,<sup>58</sup> hydroprocessing,<sup>59</sup> hydrofluoric acid alkylation,<sup>60</sup> and sour water stripping.<sup>61</sup>

A particular focus of collaborative industry work has been the mitigation of EAC risks that present the most significant risks of loss of containment, the mechanisms of which are described in other relevant chapters in this book. **Figure 11** summarizes the more common alloy/environment systems that are vulnerable to EAC in process equipment. A recent industry survey,<sup>62</sup> summarized in **Figure 12**, concluded that ~60% of

**Figure 11** Some alloy–environment systems that are vulnerable to EAC in process equipment.

industry EAC failures are associated with stainless steels, despite the fact that most process equipment is constructed from carbon and low alloy steels. This is a reflection of the vulnerability of austenitic stainless steels to chloride-induced stress corrosion cracking (SCC), particularly under thermal insulation and fireproofing.

The majority of industry guidance and recommended practice for the mitigation of EAC risks to process equipment relates to the performances of carbon and low alloy steels. The interrelation of the various cracking risks that arise in corrosive petroleum refining environments is summarized in **Figure 13**, which is adapted from a recommended practice<sup>63</sup> that is widely used in the industry. Guidelines are available for the detection, repair and mitigation of cracking in existing equipment that operates in wet hydrogen sulfide service.<sup>64,65</sup> For new or replacement equipment, mitigation of cracking due to hydrogen charging is based on the control of base metal chemistry and the hardness of welds and heat-affected zones (HAZ) within the threshold levels and, if appropriate, post-weld heat treatment (PWHT).<sup>66</sup> Sulfide stress cracking (SSC) risks are mitigated by hardness control according to NACE standard MR0103,<sup>67</sup> which was developed recently to differentiate downstream fluids (containing ammonia and/or hydrogen cyanide) from upstream fluids (containing CO<sub>2</sub> and/or chloride) that were used historically for defining both upstream and downstream sour service according to the long-established NACE standard MR0175. For ASME IX P1 or 2 steel grades, from which most equipment is constructed, there are no base material hardness requirements, but welds and HAZs are controlled within hardness number limits of 200 HB on the Brinell scale and 248 HV on the

**Figure 12** Frequency of EAC in process equipment as a function of alloy class. Reproduced from Puyear, R. B. *Corrosion Failure Mechanisms in Process Industries - A Compilation of Experience*; MTI Publication 9502-R4, Materials Technology Institute of the Process Industries, 1997.

\*Environments such as caustic, alkanolamine solutions containing CO<sub>2</sub> and/or H<sub>2</sub>S, alkaline sour waters containing carbonates.

\*\*Italicised mechanisms referred to collectively as 'wet H<sub>2</sub>S cracking' when they occur in wet hydrogen sulphide environments.

**Figure 13** Interrelationships of the various EAC mechanisms for carbon steels in corrosive petroleum refining environments. Adapted from NACE Standard Recommended Practice RP0472-2005: *Methods and Controls to Prevent In-service Environmental Cracking of Carbon Steel Weldments in Corrosive Petroleum Refining Environments*; NACE International, 2005.

Vickers scale, respectively. The corresponding risks of hydrogen-induced cracking (HIC) and stress-oriented hydrogen-induced cracking (SOHIC) in the base materials are mitigated by controlling steel chemistry and microstructure (including limits on sulfur

content and inclusion shape control) and manufacture (in particular, rolling conditions), and confirming resistance by appropriate testing.<sup>68-70</sup>

A typical example of damage to a carbon steel vessel in a wet hydrogen sulfide environment is

shown in **Figure 14**, which relates to failure of a nonstress-relieved vessel for storing crude propane, operating at 17 bar and  $\sim 50^\circ\text{C}$ . The steel vessel contained type II MnS inclusions and anomalous microstructures that rendered it vulnerable to HIC and blistering damage in an  $\text{H}_2\text{S}$ -containing aqueous phase that separated out in the vessel base within the vulnerable temperature range (commonly  $15\text{--}35^\circ\text{C}$ , but possible up to  $\sim 120^\circ\text{C}$ ). There was no associated SSC, because weld and HAZ hardnesses were below the threshold levels for cracking. By the time this damage was detected by internal inspection, the vessel was beyond repair but was rendered fit for short-term operation, while a new vessel was procured by drilling the more severe blisters externally to relieve internal stresses. EAC risks were mitigated for the replacement vessel by selecting an HIC-resistant grade of steel and appropriate welding procedures and specifying PWHT of the vessel to further mitigate the risks of SSC of the welds.

Hydrogen-related EAC mechanisms for carbon and low-alloy steels are more prevalent in the petroleum refining and petrochemical sectors than in the wider chemical industry, where SCC mechanisms dominate. There is available industry guidance on the mitigation of SCC risks that are also of interest to the petroleum refining and petrochemical sectors such as in caustic<sup>71</sup> and amine<sup>72</sup> environments, boiler feed waters<sup>73</sup> and fuel-grade ethanol.<sup>74</sup> However, guidance on the mitigation of other SCC risks for carbon and low-alloy steels such as those that arise in solutions of nitrate,<sup>75</sup>

carbonate/bicarbonate,<sup>76</sup>  $\text{CO}/\text{CO}_2$ <sup>77</sup> and hydrogen cyanide<sup>75</sup> tends to be more organization-specific and/or more widely scattered in the open literature. Nevertheless, practicable design and operating practices that mitigate SCC risks have been developed for all of these systems based on experience and experimental research to understand and dimension the factors that control initiation and propagation of cracking, as can be illustrated for the case of SCC of steels promoted by anhydrous ammonia.<sup>78</sup>

Anhydrous ammonia is stored and transported in large quantities around the world in carbon steel tanks and vessels that are mostly nonstress-relieved and operating under conditions that range from atmospheric pressure at a temperature of  $-33^\circ\text{C}$  to significant pressures at ambient temperatures. In the early 1980s, it was recognized that such storage equipment is at significant risk of SCC of welds and HAZs, as summarized in **Figure 15**. Industry-sponsored research<sup>79</sup> established that

1. Crack initiation risks increase with temperature above  $-33^\circ\text{C}$  and with steel strength.
2. Crack initiation risks increase with oxygen content and decrease with water content of the ammonia. However, water partitions preferentially into the liquid phase, so condensates from the vapor phase above a water-inhibited liquid phase may still initiate cracks.
3. Cracks propagate at relatively low velocities that reduce with time.

**Figure 14** HIC/blistering of a propane accumulator vessel base because of contact with an  $\text{H}_2\text{S}$ -containing aqueous phase but no associated SSC because the weld/HAZ hardnesses were below threshold levels.

The risk mitigation options that emerged from the research work were:

1. Reduction of initiation risks by specifying relatively soft steels and welds and/or stress relieving new vessels, if practicable, and by controlling ammonia composition in service by eliminating oxygen and/or adding a threshold amount of water if practicable.
2. Reduction of risks arising from crack propagation in service by the management of inspection and repair.

On the basis of these findings, various approaches have emerged for the management of SCC in anhydrous ammonia storages typified by that developed in

Australia,<sup>80</sup> summarized in **Table 1**. Clearly, mitigation by the use of relatively soft steels is impractical for most situations. For relatively small transport vessels, where it is impractical to control ammonia composition because of the frequency of filling and emptying operations, mitigation is achieved by a combination of thermal stress relief and relatively regular, mandatory inspections. On the other hand, for large storage vessels for which thermal stress relief is impractical, mitigation is based on the control of ammonia composition together with appropriate inspection or repair policies that may include probabilistic approaches to scheduling inspection and maintenance.<sup>81</sup>

**Figure 15** Welds in nonstress-relieved anhydrous ammonia storages may be vulnerable to SCC, depending on the relative contents of oxygen and water in the ammonia.<sup>78,79</sup>

**Table 1** Australian<sup>80</sup> approach to the management of carbon steel storage and transport vessels to mitigate risks arising from SCC promoted by anhydrous ammonia

Mitigation option	Storage tanks	Road/rail tankers
Use steels <300 MPa yield	Most steels stronger	Most steels are Q & T and stronger
Stress relieve	Impractical	Mandatory if >300 MPa yield
Eliminate oxygen	Minimize inspection frequency, control recommissioning	Impractical
Add 0.2% water	Normal practice	Vapor space?
Manage inspection/repair	Develop noninvasive inspection and fitness for service (FFS) approaches	Mandatory internal inspection every 1 or 2 years

Regarding the mitigation of industry EAC risks to materials other than steels, stress relief is rarely used and mitigation is more focused on the avoidance of material/environment combinations that present risks. Guidance also tends to be more organization-specific than for steels and/or more widely scattered in the open literature, as for the avoidance of the most frequent cause of failure, the chloride-induced SCC of austenitic stainless steels. Some sources are comprehensive in scope<sup>75</sup> while others relate to specific process duties such as thermal insulation<sup>20</sup> and water-cooled heat exchangers.<sup>82</sup> Guidance on the avoidance of caustic cracking of stainless steels is more limited but there are sources that define environmental conditions that present risks.<sup>83</sup> However, there are detailed recommended practices for mitigating the risks of polythionic acid-induced SCC of austenitic stainless steels and other austenitic alloys during the shutdown of refinery equipment<sup>84</sup> and for avoiding sulfide-induced stress cracking (SSC) of stainless steels and nickel, cobalt, titanium, aluminum, and copper alloys in corrosive petroleum refining environments containing H<sub>2</sub>S.<sup>67</sup>

The author's own unpublished survey of EAC experience over a 20-year period within a world scale chemical company concluded that EAC failures arose principally (~70% of all cases) from failure to identify or control environments that presented a significant threat due to lack of awareness of the EAC potential of an environment, inadequate chemistry definition, inadequate chemistry control, or unpredicted contamination with EAC-promoting chemicals. The biggest single cause of unpredicted EAC failure was the development of EAC-promoting microenvironments at specific equipment locations and stages of operation, and of this group the commonest example (~30% of all cases) was ESCC of austenitic stainless steels. Of the remaining cases, ~20% arose from materials causes, either selection of the wrong material or of the right material in the wrong condition, and a small minority (~10% of all cases) arose from failure to control stress, principally, as a result of inefficient stress relief.

#### 4.40.6 Mitigation of Corrosion Risks During Operation

Operating process equipment is not managed by corrosion engineers but by other professionals whose goals include the development and maintenance of equipment to provide increased availability and reliability without jeopardizing the organization's SHE

obligations that require the avoidance of incidents and assurance of structural integrity. The processes that may be adopted to manage corrosion are reviewed in detail in a separate chapter in this book. However, in most organizations the management of corrosion is not a separate functional activity but is integrated into more familiar asset management functions such as production and maintenance. Within this framework, the management of corrosion during operation is defined by two key objectives:

1. Ensuring that the design intents in relation to the mitigation of corrosion risks are delivered during operation. This requires that processes are operated within the design envelope in relation to all of the factors that can influence corrosion risks such as the compositions, temperatures and velocities of process fluids, the intensities of heat fluxes, etc. It also requires that corrosion control practices that were specified in design, such as inhibitor addition, electrochemical protection, etc. are operated continuously to design specification.
2. Dimensioning and understanding the corrosion performance of equipment by inspection and monitoring, and embedding corrosion performance data in asset development and maintenance databases so that corrosion risk mitigation is integral to the maintenance management processes that capture history and learning in pursuit of reduced maintenance costs and increased reliability and availability.

The delivery of these objectives requires the promotion of corrosion awareness and commitment amongst production and maintenance personnel who are accountable for delivering manufacturing performance. Effective corrosion management derives from influential corrosion professionals operating within the appropriate management systems.

Central to the management of corrosion during operation is assurance of the structural integrity of process equipment and this has been enabled by continuing developments in protocols and techniques for the inspection and monitoring of process equipment that are described in separate chapters of this book:

1. RBI procedures<sup>85–87</sup> are now the norm for process equipment. Large companies have developed their own protocols, and proprietary procedures are available from numerous sources. An essential first stage for any organization is the calibration of the risk/consequences matrix by defining acceptance criteria for the probability and

consequences of failure within a specified time-scale. This is a team activity, requiring contributions from equipment specialists and inspectors, process engineers, and operations and maintenance personnel in addition to materials/corrosion specialists. The required effort and cost of an RBI process increases with the period under consideration and a common practice is to focus on a limited number of turnaround periods rather than the full design life of equipment. It is important that the risks of external as well as internal corrosion are evaluated for equipment items. As indicated previously, the semiquantitative evaluation of corrosion risks is normally regarded as sufficient for process equipment, based on the mostly empirical corrosion data that are used to predict corrosion performance, the reliability of which is classified as high, medium, or low, depending on the source.<sup>88</sup> The contributions of materials and corrosion specialists are crucial to the accurate evaluation of risks. Key outputs of RBI processes are risk rankings for equipment items and corresponding inspection plans and other risk mitigation activities to be adopted. Inspection plans detail the inspection methods to be adopted in defined areas and locations, and the timing of examinations. Other risk mitigation activities include fitness for service (FFS) evaluation based on codified<sup>89</sup> defect and remnant life assessment procedures that are described in a separate chapter in this book, the adoption of methods to monitor deterioration rates and their variation, and equipment repair or replacement, or modification or redesign. Anticipated reductions in risk levels are predicted after inspection plans and other risk mitigation activities are implemented. The key benefit of RBI has been to focus management attention and effort on the most significant risks to the structural integrity of equipment, including corrosion risks. However, RBI has also delivered significant economic benefits, due not least to improvements in the planning and scheduling of maintenance.

2. Noninvasive NDE technologies are available, including acoustic emission (AE) and scanning ultrasonics (UT) that allow the condition of equipment to be established while the equipment continues to operate, without the need to shut down and prepare equipment for entry. AE detects and locates internal flaws in metal or FRP-pressurized systems by detecting acoustic emissions from defect micropagation processes with external, surface-mounted,

piezoelectric probes. Emissions are triggered by raising the pressure beyond the design or previous operating levels and their amplitude is a guide to the severity of the defect. The entire structure is assessed in one; rapid operation and triangulation techniques allow emissions to be positioned within  $\sim 10$  mm. Defects that have been located by AE can be sized using external ultrasonic techniques online if permitted by access and operating temperatures. Automated C-scan ultrasonic techniques allow mapping of corrosion distribution by computer control, processing, storage and imaging of ultrasonic signals. P-scan techniques produce 3-D reconstructions of defect locations and sizes from robotic manipulation of probes and computer processing of signals. Having been located and sized, defects can be assessed for their significance using appropriate FFS<sup>89</sup> procedures, allowing the entire structural integrity evaluation process to be undertaken without interrupting production.

3. Online corrosion monitoring technologies are available that are noninvasive and allow monitoring of equipment directly without having to resort to probes, including hydrogen permeation,<sup>90</sup> thin layer activation (TLA),<sup>91</sup> field signature monitoring (FSM)<sup>92</sup> and pulsed eddy current (PEC).<sup>93</sup> Technologies are also available based on electrochemical noise (ECN)<sup>94</sup> that is sensitive in real time and to localized corrosion. Examples of the uses of corrosion monitoring to deliver increased plant availability are illustrated in **Figures 16 and 17**. The case illustrated in **Figure 16** relates to a well known hydrocracker corrosion problem in refineries. As shown in the simplified process flow diagram, reactor effluent, a mixture of hydrogen, hydrogen sulfide, hydrocarbons and salts such as ammonium bisulfide ( $\text{NH}_4\text{HS}$ ), is cooled in air coolers upstream of which water is injected to prevent corrosive salt accumulation in equipment. In the particular case,<sup>95</sup> the air cooler exit pipework constructed in carbon steel suffered  $\text{NH}_4\text{HS}$ -induced, flow-assisted corrosion at higher rates than anticipated in the design. Corrosion rates were monitored online using PEC sensors that were strapped onto pipes as shown in **Figure 16**. PEC offers significant advantages over ultrasonic determinations of wall thickness because of its greater repeatability, which allows corrosion rates to be determined more rapidly. Data typified by that shown in **Figure 16** for an elbow in an exit pipe provided justification for an extended run-time while replacement material was procured and a shutdown was planned. The case illustrated in

**Figure 16** Online, pulsed eddy current (PEC) monitoring of carbon steel piping wall thickness provides justification for an extended hydrocracker run-time to procure replacement material and plan a shutdown. Reproduced from Crouzen, P. C. N.; Munns, I. J.; Verstijnen, W.; Hulsey, R. C. In *Corrosion 2006*, NACE International, 2006; Paper 06312.

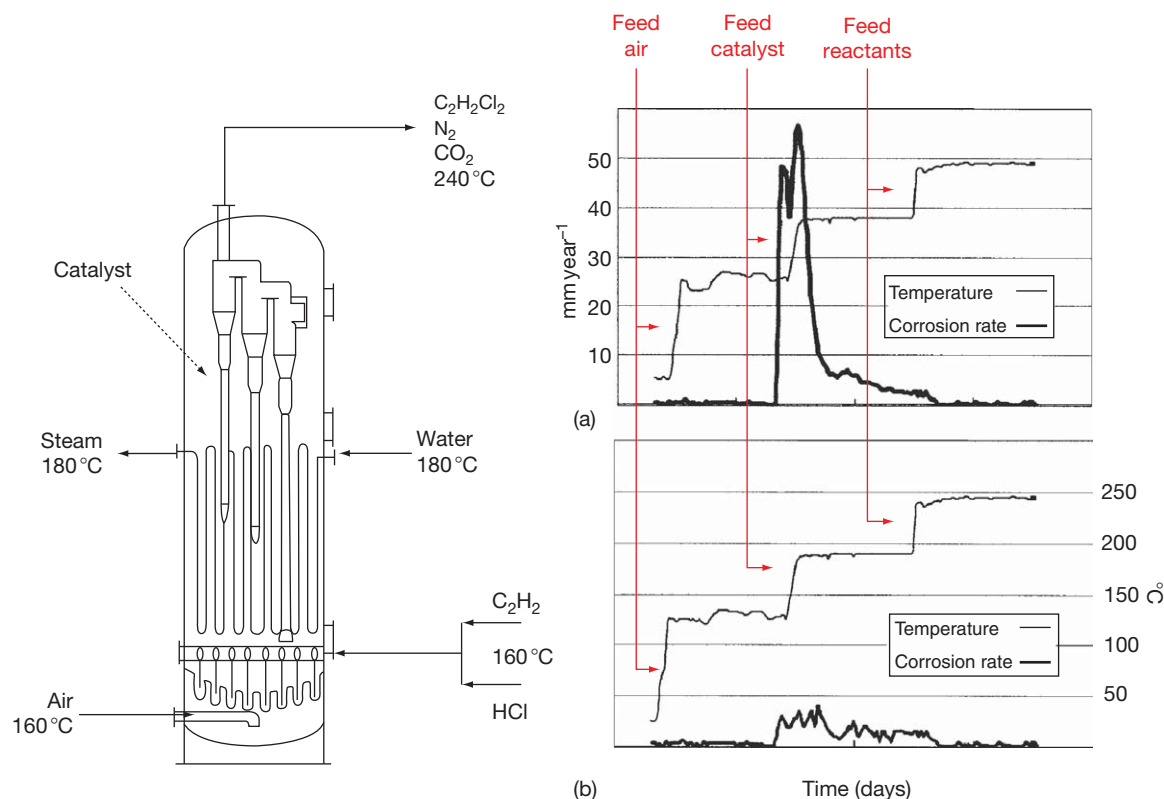

**Figure 17** relates to the start-up stage of an ethylene dichloride (EDC), fluidized bed reactor. Reactors are constructed typically in carbon and low alloy steels and relevant process flows in the reactor are shown schematically in **Figure 17**. The greatest risk of corrosion occurs during plant start up in the event that condensation of the hydrochloric acid feed occurs on steel surfaces. In the particular case,<sup>96</sup> steel reactor internals had suffered excessive corrosion and real-time ECN monitoring using an appropriate multielement corrosion probe established that corrosion rates up to  $\sim 50 \text{ mm year}^{-1}$  were experienced during start up due to condensation because the catalyst feed temperature ( $100^\circ\text{C}$ ) was

too low and the time interval between the hot ( $160^\circ\text{C}$ ) air and catalyst feeds to the reactor was too short. Typical temperature and corrosion rate profiles before and after adopting a revised startup procedure involving a higher catalyst feed temperature ( $140^\circ\text{C}$ ) and a longer time interval are shown in **Figure 17**. As a result of these changes, corrosion rates during start up were reduced by a factor of five resulting in extended lives for carbon steel internals and a significant (2%) increase in the availability of the reactor.

#### 4.40.7 Corrosion Risk Management Costs and Benefits

A recent study<sup>19</sup> of the UK petrochemicals/chemicals sector estimated that total expenditure on corrosion management amounted to  $\sim 4.5\%$  of industry turnover. The majority of this expenditure was spent optimally and beneficially, comprising the inevitable costs of mitigating the corrosion risks associated with the processing corrosive and hazardous fluids to add value without incurring unacceptable financial or SHE consequences. However, two areas of avoidable expenditure were identified:

1. In the cases of ageing, individual plants and sites that were designed, fabricated and protected to standards now recognized as inadequate, estimated expenditure on corrosion management as high as  $\sim 9\%$  of turnover was identified. The great majority of this expenditure was associated with historical deficiencies in the awareness and management of external corrosion of carbon and stainless steels under thermal insulation and fire-proofing that have resulted in major remedial expenditure to mitigate risks. This emerged as the largest individual corrosion cost to the industry but it should be a one-off legacy cost that declines as the risks to replacement or new equipment are mitigated by improved design, specification and fabrication practices.
2. It was estimated that  $\sim 15\%$  of the total expenditure on corrosion was associated with problems for which there are proven, economic solutions and was avoidable by better application of existing corrosion control technology and management practices. Some of the wasted expenditure arose from deficient materials selection and design practices relating to the mitigation of risks such as the localized corrosion of stainless steels and nickel alloy equipment, particularly at welds; erosion and

**Figure 17** Corrosion rate profiles obtained by ECN monitoring during start up of an EDC reactor (a) before and (b) after implementing measures to prevent condensation of HCl on internal steel coil/pipe surfaces. Reproduced from Ohtsu, T.; Miyazawa, M. In *Corrosion 2007*, NACE International, 2007; Paper 07266.

erosion corrosion in piping and heat exchangers; galvanic corrosion, particularly at specified transitions from one material to another in piping; the corrosion of heating/cooling coils in batch vessels, etc. Other wasted expenditure arose from deficiencies in the management of corrosion in operation, not least the control of corrosion in cooling water and steam raising equipment.

The UK study also identified several developing and new processes for which corrosion risks present significant barriers to commercialization because cost-effective mitigation practices have yet to emerge, typified by processes that promote metal dusting and organic oxidation processes undertaken in supercritical water (SCW):

1. Metal dusting is described in a separate chapter in this book and is a risk under process conditions that favor carbon deposition as a result of the disproportionation and/or reduction of carbon monoxide in gas mixtures that also contain hydrogen as summarized in [Figure 18](#). A common

example is synthesis gases that are formed by the steam reforming of hydrocarbons. Carbon deposition is catalyzed on surfaces that contain iron, nickel, and cobalt and the rate of carbon uptake is a balance between thermodynamic and kinetic driving forces. Metal dusting is a relatively low-temperature phenomenon with rates that generally peak in the temperature range  $\sim 400\text{--}800^\circ\text{C}$ . Penetration of carbon reduces ductility and results in transformation to a mixture of oxide, alloy and carbon particles which can shed resulting in general or localized corrosion that can be very rapid.<sup>97</sup> All high temperature alloys are vulnerable to metal dusting but risks can be mitigated to some extent by the incorporation of strong oxide promoters such as chromium, aluminum and silicon, either in the alloy itself or on the surface by appropriate coating processes. In theory, risks may also be mitigated by increasing the ratio of steam or including catalyst poisons such as hydrogen sulfide in the process gas. However, process efficiency considerations favor lower rather than

higher steam ratios and catalyst poisoning concerns preclude sulfide additions. At the current state of art, robust and cost-effective materials solutions have yet to emerge and the migration of several world scale processes to the most efficient operating conditions remains inhibited by metal dusting risks.

- Over the past ~10 years there has been considerable interest in the potential of SCW as a solvent.

Solubility behavior is reversed in SCW so that organic materials are soluble and inorganic salts insoluble, allowing single-phase oxidation of organic materials (SCWO). Much of the early research interest has been focused on the development of processes for the destruction of hazardous wastes, as summarized in Figure 19. However, there has also been interest in the development of SCWO processes that may offer economic advantages over

**Figure 18** Equilibrium ratios at unit carbon activity versus temperature for CO disproportionation and reduction processes – metal dusting threatens equipment operating at temperatures below unit carbon activity in any gas composition.

**Figure 19** Typical conditions and products of organic waste destruction by supercritical water oxidation (SCWO).

conventional processes for commercially important organic oxidations such as the oxidation of paraxylene to terephthalic acid.<sup>98</sup> Commercial application of SCWO technology requires materials that are resistant to corrosion under super- and subcritical conditions, at temperatures above  $\sim 300^\circ\text{C}$ . In processes where mineral acids are significant products of SCW oxidation, such as those summarized in **Figure 19**, corrosion is a potential show-stopper. In general, stainless steels are insufficiently resistant to corrosion, nickel alloys have shown major corrosion vulnerabilities, and although titanium and zirconium have shown useful corrosion resistances, they have other limitations relating to their strength and resistance to ignition at the prevailing temperatures and high oxygen pressures. Economic, robust, long-term materials solutions have proved elusive.<sup>99</sup>

#### 4.40.8 Future Trends in Process Equipment

The current trend to increasingly large, single stream plants seems likely to continue in the refining, petrochemical and commodity chemicals industries. For example, single stream sulfuric acid plants are

currently under construction with capacities of  $4\text{--}5000\text{ t day}^{-1}$ . There are challenges relating to the fabrication of extremely large vessels and the logistics of transporting them around the world, not to mention the operability of extremely large equipment and the high cost of unreliability. However, large capital cost savings provide the incentive that favors the trend.

Against the trend, there is growing interest in the advantages of microscale manufacture using micro-equipment, of the type shown in **Figure 20**. A key advantage of microequipment<sup>98,99</sup> is the possible reduction of manufacture, reaction and transport to the same timescales. Diffusion distances are reduced to minimize residence times, obviating the requirements for mixing/velocity in conventional equipment. This requires small flow channels, typically submicron to 1 mm with high surface-to-volume ratio and reduced residence times and process volumes. Lower diffusion resistances favor high catalyst selectivity. A manufacturing plant comprises a multitude of small or lab scale reactors.

Materials and fabrication techniques are drawn from the microelectronics and semiconductor industries. Materials include silicon, glass, ceramics and polymers as well as metals, fabricated with techniques that include lithography, electroplating, molding, etching,

**Figure 20** Microprocess equipment for fine chemicals/pharmaceuticals manufacture: (a) liquid-liquid reactor,<sup>99</sup> (b) heat exchangers,<sup>98</sup> and (c) microstructured reactor with equivalent throughput to continuous stirred tank reactor in the background.<sup>99</sup>

micromachining, laser ablation, etc. Catalysts are applied using surface enhancement techniques such as anodic oxidation, or impregnation using PVD/CVD or ion implantation. This is clearly very different territory from traditional materials and corrosion engineering!

It remains to be seen what impact microscale manufacture will have on the industry as a whole. To date, interest seems to be focused mainly in the fine chemicals and pharmaceuticals sectors, where it has been strong enough to promote acquisitions of companies that specialize in the fabrication of such equipment.

#### 4.40.9 The Current Corrosion Risk Management Scorecard

The petrochemical/chemical industry has seen major advances in equipment reliability, availability, and SHE performances because of advances in corrosion understanding, control technology and management practices. However, unpredicted, SHE-threatening and/or expensive incidents continue to occur. Most are avoidable, arising from deficiencies in awareness and/or management of recognized corrosion risks for which there are proven, economic solutions, but some arise from problems for which there are not yet proven, economic solutions. Significant corrosion challenges/opportunities remain to be addressed.

## Glossary

**Barrel** A (depreciated) unit of volume, used for measuring production ( $1 \text{ barrel} \approx 0.159 \text{ m}^3$ ).

**Consequence of failure** The impact of components/equipment failure on health and safety, production, and environmental parameters.

**Corrosion management** (1) Defined as that part of the overall operation management program aiming at the implementation of the Corrosion Policy (2) Organization set-up and operational process to ensure corrosion control, inspection, monitoring, and assessment plans are implemented to optimize asset integrity.

**Corrosion risk assessment** A formalized process in which the combination of the consequences of failure and the likelihood of failure is assessed to identify the level of risk of ongoing operations. A corrosion risk assessment is used to (1) identify items in which design and/or corrosion control plans should be readdressed to reduce risk (2) to assist in defining the maintenance and monitoring tasks that should be implemented (see RBI).

**Direct assessment** Formalized method for reviewing information relating to the possible degradation of a pipeline due to corrosion (internal or external) to identify areas for excavation and physical direct assessment as part of fitness-for-service study.

**Fitness-for-service** Engineering assessment to determine the ability of a component to perform its function as designed in a safe

manner and in accordance with the relevant regulations (also referred to as fitness-for-purpose or fitness-for-use).

**Key point indicator** An operational process or management parameter that can be measured and tracked during operations to assess the high level performance of critical items/activities.

**Latent condition** An undiagnosed or unrecognized flaw or defect in data, data management systems, documents, procedures, and guidance/standards that gives rise to human errors.

**Likelihood of failure** A method used to prioritize components/facilities that are subject to possible failure. Normally used in qualitative or semiquantitative risk assessments (some times used interchangeably with Probability of Failure).

**Probability of failure** A method used to prioritize components/facilities that are subject to possible failure. Normally used in as part of a fully quantitative risk assessment (some-times used interchangeably with Likelihood of Failure).

**Risk-based inspection** A method for prioritizing and defining inspection activities to focus on items that are considered to have the highest risk of degradation, as defined by the combination of consequence and likelihood.

**Safety, health and environment** A formal process for defining policy and implementing strategy associated with the

management of the safety and health of people in the vicinity of the facility, and the impact on the environment surrounding the facility.

**Total quality management** Is a business management strategy aimed at embedding awareness of quality in all organizational processes.

**WG** Wet gas

## 4.41.1 Introduction

### 4.41.1.1 Outline

This chapter addresses issues concerned specifically with the management of corrosion in oil and gas production equipment both onshore and offshore and from subsurface, through pipeline systems and process plant to storage and export facilities. The industry covers a wide range of assets of differing ages and designs that operate with varying internal and external environments. Such infrastructures also reflect particular company cultures and the equipment designs/operations must meet different legislative requirements around the world. It is not possible to cover every aspect in this review, but the aim is to provide a general approach to corrosion risk mitigation and management of typical issues encountered in the field. The message is that ‘one size does not fit all’ and each case must be treated individually with appropriate assessments, reviews, and audits throughout the project life.

Corrosion management in the oil and gas industry follows the same requirements as outlined in the corrosion management overview chapter in this book. In fact, modern corrosion management across all industries evolved out of procedures and systems developed specifically for oil and gas production facilities, where the emphasis has been on ‘managing assets constructed from carbon steels that are inherently at risk of corrosion deterioration.’<sup>1</sup>

Corrosion management for oil and gas operations has been the subject of considerable discussion in the industry. In 2001, the UK Health and Safety Executive (HSE) published a general guidance document aimed at

UK offshore production facilities and focused on internal corrosion threats.<sup>2</sup> This has recently been updated by the UK Energy Institute<sup>3</sup> and expanded to cover all aspects of oil and gas processing, including onshore and external corrosion. Elsewhere, particularly North America, there have been developments in the requirements for corrosion management of pipeline systems, which has resulted in the development of *direct assessment systems*, which are described in [Section 4.41.6.8](#).

The introduction to this chapter outlines the causes of corrosion damage found in equipment items, including the location, type, related problems, and mitigation measures. Aspects of corrosion management specific to oil and gas production are introduced in [Section 4.41.2](#) and then the main focus is on the various project phases where specific concerns are addressed from the front end engineering design (FEED) in [Section 4.41.3](#) and the requirements for design and detailed design in [Section 4.41.4](#) to fabrication, construction, and commissioning in [Section 4.41.5](#) and operations in [Section 4.41.6](#). The objective is to provide a logical structure based on typical project timeliness that is useful to both specialists and nonspecialists.

### 4.41.1.2 Overview of Oil and Gas Industry Corrosion

The primary objective of oil and gas production is the cost-effective and safe abstraction of hydrocarbons from fields, reservoirs, and local wells into flow lines and gathering lines, separate oil and gas from any produced water and then export, usually through pipelines, to storage prior to refining or transfer to a tanker or export pipeline. All these facilities pose a potential risk for health and safety, environmental and commercial concerns. Secondary facilities, including water injection, firewater, produced water disposal, etc. are also subject to corrosion threats and while failure of these systems may not present a safety health and environmental (SHE) risk, it could result in the reduction/cessation of production with consequential commercial implications.

The industry covers a wide range of assets, both onshore and offshore, and it is not possible to address every design in this review nor to cover macroeconomics, seismic, and political risk. Also each field, facility, and asset will have its own specific corrosion issues that result from local produced fluid compositions, water cuts and changing chemistries, CO<sub>2</sub> and H<sub>2</sub>S content, flow conditions and possible microbiological contamination during drilling and production. In many cases, external environments also provide a

major threat, ranging from subsea, offshore processing, and onshore conditions with conditions ranging from cold arctic to hot desert. In practice, all these issues have to be considered if the effects of corrosion damage are to be mitigated and managed effectively.

Other factors that influence the management of corrosion include the age, design, operation, organizational structure, and culture and maintenance philosophies, as well as local and corporate SHE obligations. Key concerns for installations are the prevention of incidents resulting from sudden or catastrophic failure and the prevention of hydrocarbon releases. Hydrocarbon fluids are flammable and produced fluids that contain hydrogen sulfide, a toxic and corrosive gas, are major hazards. There has always been an emphasis to design, construct, operate, and maintain the facilities in a safe manner, but what has changed over the past 15–20 years is that SHE issues now require that any procedures that are adopted need to be increasingly risk based and auditable, while the manner in which activities are conducted requires clearly defined reporting routes and appropriate actions from identified and responsible personnel.

For economic reasons, the majority of oil and gas facilities are constructed from carbon and low-alloy steels that are susceptible to both internal corrosion from the acidic process conditions and external corrosion from the environment. Hence, standard corrosion mitigation procedures are employed by the industry, such as chemical injection into produced fluids and the application of corrosion-resistant coatings plus cathodic protection to the outside of buried or immersed pipelines, as will be outlined below. Industry emphasis is on production deliverability and reliability and the efficiency of the overall process by the elimination of pinch points or poor practices that limit any specific areas of activity. A concern is that the experience and benefits from one field cannot be transferred automatically to a new development or existing facility without a management assessment of the risks arising from the changes and an understanding of the differences between locations, conditions and staff experience. A properly developed and well-functioning corrosion management system should be able to address such issues by highlighting the areas of varying risk, having in place suitable monitoring systems that are able to convert data into reports that trigger appropriate and timely management decisions.

Thus, although general principles are addressed in this chapter, it is essential that in practice each case is assessed on an individual basis. Corrosion risks can be identified, mitigated and managed effectively but

require appropriate tools and practices, agreed procedures, clear processes with logical sequential steps, suitable organizational structures and adequate resources.

The different corrosion threats (internal and external) applicable to oil and gas production facilities are given in the *Corrosion Threats Handbook – Upstream Oil and Gas Production*.<sup>4</sup> Those relating to main production facilities are summarized in **Figure 1**. Other corrosion threats, associated with storage, transportation, and various utility services necessary for oil and gas production, are also applicable.<sup>4</sup>

Details of the different corrosion mechanisms are described in other chapters elsewhere in this book and include:

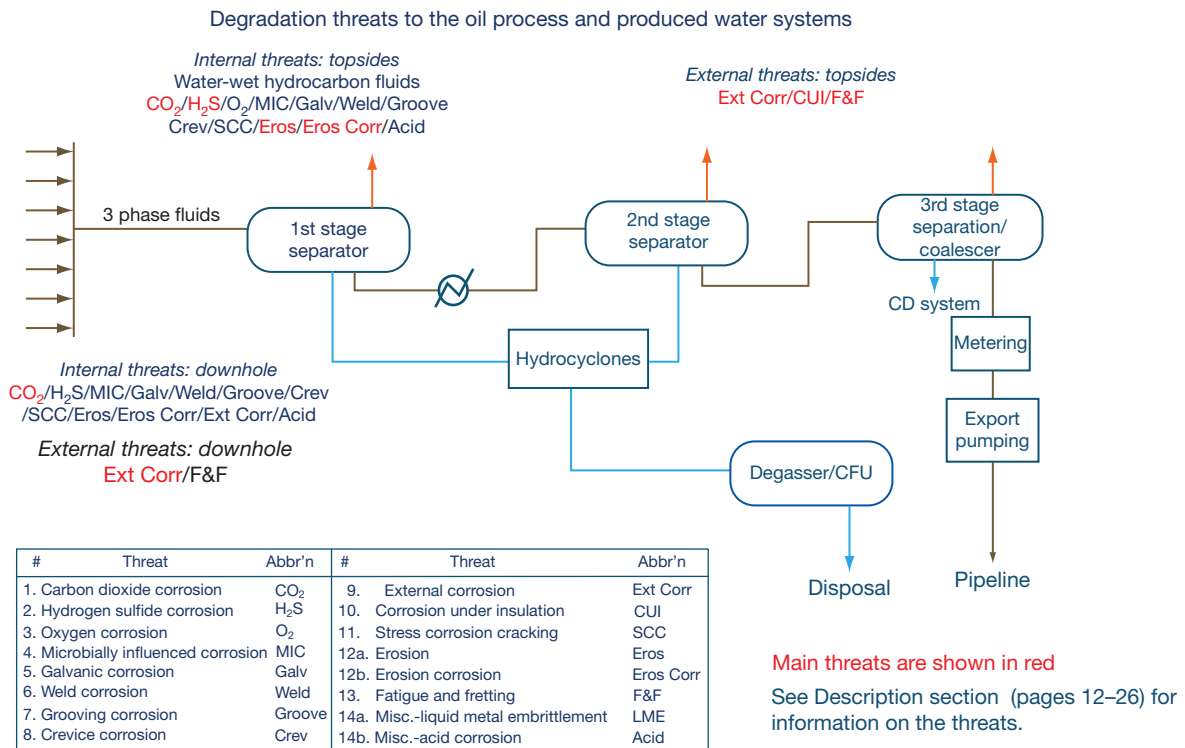

**a. Internal corrosion/degradation:**

- ‘Sweet’ corrosion due to the formation of carbonic acid in produced waters from dissolved CO<sub>2</sub>.
- ‘Sour’ corrosion due to the formation of acidic conditions from dissolved H<sub>2</sub>S.
- Microbiologically influence corrosion (MIC) due principally to the presence of sulfate reducing bacteria (SRB).
- Oxygen corrosion in water injection facilities due to an inadequate removal of oxygen and associated with high flow rates.
- Galvanic corrosion caused by direct electrical connection of different materials/alloys to the same conductive environment.
- Erosion and erosion corrosion, due to particulates, mainly sand, in the production stream.
- Flow-assisted corrosion associated with effect of surface shear on the stability of protective films on the steel surface.
- Environmentally assisted cracking (EAC), in particular:
  - chloride stress corrosion cracking (CSCC) of austenitic stainless steels and corrosion-resistant alloys;
  - sulfide stress corrosion cracking (SSCC) of carbon steels, austenitic stainless steels, and corrosion-resistant alloys (CRA);
  - hydrogen induced cracking (HIC) of carbon steels

**b. External corrosion/degradation**

- Atmospheric corrosion.
- Corrosion under insulation(CUI).
- Corrosion in seawater/fresh water.
- Corrosion in soils.

A range of different corrosion control methods is adopted that are described in detail in other chapters, including:

**Figure 1** Example of corrosion threats in oil/gas processing units. Reproduced from Corrosion Threats Handbook – Upstream Oil and Gas Production; Energy Institute and Oil and Gas UK: London, 2008.

- use of corrosion resistant alloy (CRA);
- use of chemical treatments, including use of corrosion inhibitors and biocides;
- use of protective coatings (external and internal organic and metallic);
- use of cathodic protection (CP), external and internal;
- process modification such as deoxygenation and dehydration.

#### 4.41.1.3 Areas of Corrosion Risk and Industry Mitigation Approach

The following section provides a background to the different components/facilities used in oil and gas production and processing, and the different corrosion issues relating to them.

##### 4.41.1.3.1 Corrosion subsurface

Wells typically comprise

- **casing** – carbon steel sections, that may be pre-coated, cemented to the formation;
- **bottom hole perforations** – explosively formed holes to allow reservoir fluids in the strata to enter the well bottom;

- **production tubulars** – sections of drawn pipe screwed together to form a continuous string for transport of produced fluids;
- **down-hole safety valve**;
- **annulus fluid and packer** – high-density fluid between the tubular string and the casing that helps to balance the well to surface pressure;
- **well head valve** and equipment;
- **cellar** – surface platform/foundations that holds well equipment in position;
- **gas injection valves** – enable low-pressure oil wells to maintain production;
- **inhibitor injection valve** – provides a continuous feed of corrosion inhibitor into the produced fluids via a thin ‘spaghetti’ tube inserted down the annulus.

##### 4.41.1.3.1.1 Corrosion issues

Drilling a well could introduce SRB down-hole into the reservoir unless the monitoring and biocide treating of the aqueous drilling mud is carefully controlled. Well casings may be in contact with corrosive aquifers above the reservoir. Wells with high multiphase flow are subject to impingement and ‘mesa’ type elongated erosion–corrosion pits. Wellhead equipment, valves, and choke bodies are susceptible to erosion corrosion

and severe localized corrosion especially with high temperature, high chloride content fluids and high-pressure gas wells. Maintenance of flow through the reservoir strata and removal of scale deposits from tubular goods may require chemical cleaning with corrosive chemicals (acids and acidic solutions of complexing reagent). These fracing/cleaning fluids, introduced as a 'squeeze' treatment, can cause significant corrosion when returned up the well. Materials must be specifically selected for their mechanical and corrosion resistance properties, particularly safety critical items.

Typical corrosion related problems include:

- uniform/general corrosion caused by carbon dioxide and hydrogen sulfide in reservoir fluids and acids/chemicals in treating fluids;
- pitting due to chlorides and sour environments under conditions of high chloride content and temperature;
- hydrogen damage of susceptible steels in sour systems;
- erosion corrosion due to high velocities of fluids (gas slugs);
- introduction of corrosive gas during gas lift operation;
- SRB contamination of annular fluids and injection waters.

Corrosion mitigation includes:

- CP of external well casing;
- selection of 'fit-for-service' tubular steel goods/CRA/nonmetallic linings;
- down-hole inspection (wireline tools);
- use of corrosion inhibitors – squeeze/continuous injection;
- use of biocides;
- topside monitoring of produced fluids.

#### 4.41.1.3.2 Corrosion in pipeline systems

Flow-lines, gathering lines, interfield trunk and export lines are typically constructed from rolled low-alloy steels, the wall thickness of which is determined by the design/operating pressure, the service duty (sweet or sour) and the required corrosion allowance. Internal corrosion is typically mitigated by chemical treating and/or pH control together with regular maintenance pigging, and effectiveness is confirmed by inspection (including intelligent pigs) and online monitoring. In some cases internal coatings or use of linings (with either CRA or non-metallic systems). External corrosion mitigation depends on the location. Above ground lines may be uncoated in dry desert regions but coated

in more humid/coastal areas. Buried/immersed lines have a primary protection from a barrier coating plus CP. Associated equipment includes manifolds, pumps/compressors, and valves, all of which may be susceptible to corrosion attack and hydrogen damage.

##### 4.41.1.3.2.1 Corrosion issues

Multiphase lines are normally designed to operate under turbulent stratified flow conditions (liquid at the bottom, gas phase at the top) but slugging flow or gas/sand impingement may occur depending on the relative gas/liquid velocities and particle content. Some lines have a significant temperature profile that, together with the topography and bends/elbows/changes of diameter, can influence areas of water drop out, hold-up, and slugging. Bottom-of-the-line-corrosion generally occurs as water cuts increase and the fluid is no longer a water-in-oil emulsion, but local grooves (<6 mm wide) may occur at the bottom of lines with low water cuts (<10%). Such conditions may occur under low fluid velocities or when enhanced water coalescence causes water-in-oil emulsions to break down. A minimum flow (typically  $>1 \text{ m s}^{-1}$ ) is required to maintain particles in suspension and prevent sludge build-up. Fluid flow is often restricted to minimize erosion problems that is,  $<15 \text{ m s}^{-1}$  for liquids and  $<20 \text{ m s}^{-1}$  for gas.

Flow lines have a relatively small diameter and are not usually provided with launch/retrieval facilities for the deployment of cleaning pigs; hence, corrosion is often associated with water drop-out, deposits, and microbiologically contaminated sludge. Scale deposition can be a considerable problem in some fields. Scale control chemicals can limit the deposition but may lead to precipitates in the bulk fluid, these small crystals may form a sludge deposit if the flow conditions are not maintained at a high enough value ( $>1 \text{ m s}^{-1}$ ).

Internal corrosion in lines carrying produced/separated fluids results from  $\text{CO}_2/\text{H}_2\text{S}$  and in the lines carrying water for injection, fire mains, wash down, etc. from dissolved oxygen and MIC. Corrosion damage includes:

- metal wastage due to fluid corrosivity;
- localized pitting, especially in sour systems;
- grooving corrosion, especially where moderate water cuts result in a thin free water phase at the bottom of the pipeline;
- erosion corrosion at elbows, bends, riser sections or downstream of restrictions and when slugging flow is present;

- pitting/crevice type corrosion under deposits, debris and scales;
- local areas of attack due to water-drop out at low spots;
- microbiologically induced corrosion due to contamination through water injection and hydro test fluids;
- pipe-wall delamination and cracks due to hydrogen damage (HIC, SOHIC) and through-wall cracks due to SSCC.

External corrosion results from exposure to natural environments such as soils, immersion in or contact with seawater, etc. and local atmospheres. Corrosion damage takes many forms and includes:

- wastage and pitting that will be particularly severe for unprotected pipes that are buried in deaerated wet clay soils or in estuarine environments due to anaerobic SRB;
- stress corrosion cracking (SCC) due to carbonate/bicarbonate environments that may develop over time and/or hydrogen generated by excessive CP current;
- stray current effects from other CP systems, DC railways and welding; and
- telluric currents due to the Earth's magnetic field.

Corrosion mitigation options for pipelines include:

- selection of appropriate steels and weld procedures for either sweet ( $\text{CO}_2$ ) or sour ( $\text{CO}_2/\text{H}_2\text{S}$ ) service; this may require use of CRAs (either as solid pipe or as lined pipe) or use of nonmetallic pipe materials;
- inspections (pigging) to detect thinning, pitting and cracks;
- use of corrosion inhibitors by continuous injection and/or batch treatment;
- online monitoring to identify changes and control chemical treatments;
- use of biocides in batch treatments;
- control of process fluid compositions for example, dehydration of gases, removal of  $\text{H}_2\text{S}$ , pH control of wet gas (WG) lines, etc.;
- use of internal coatings, subject to concerns as to pinholes and crevice corrosion;
- use of internal linings, either non-metallic or CRA clad systems;
- coating of external walls;
- CP of buried and immersed lines and monitoring of CP systems and coating defect location, using techniques such as close interval potential survey (CIPS) and DC voltage gradient (DCVG) surveys.

#### 4.41.1.3.3 Corrosion in process plant

Equipment such as separation vessels/trains are used to separate comingled produced fluids into oil and gas/condensate to aid transportation and downstream processing. Associated items include vessel internals, electrostatic precipitators, piping between separators, desalters, knockout drums, valves, pumps, and compressors. Other areas include produced water plant, utility systems for steam generation, cooling systems and storage tanks for separated products and chemicals.

Main concerns center on:

- wet gas streams that are cleaned up in gas separation vessels, compressed, cooled, often dried and exported via a gas line, and/or used for gas reinjection;
- wet crude handling streams comprising dehydrators, desalters and a crude oil pump and export-line;
- brine phase streams with water-oil separation or stripping sections to remove oil residues, after which the water is discharged/disposed of down-hole via injection pumps used to maintain reservoir pressures.

##### 4.41.1.3.3.1 Corrosion issues

Corrosion and pitting usually occur at water-wet surfaces in the system. High-risk areas are vessel bottoms (in contact with produced water), wet gas lines downstream of compressors, water lines, and tanks containing oil, from which water droplets may coalesce and drop-out. Three phase separators/vessels, constructed from low-alloy steel materials, and containing wet gases are usually completely coated internally with high build coatings (epoxy reinforced with glass flake,  $>300\text{ }\mu\text{m}$ ) in water immersed regions and  $200\text{--}300\text{ }\mu\text{m}$  in water splash/condensation/water carry over regions in gas spaces. CP may also be installed in the water-containing vessel bottoms. Where conditions are particularly aggressive internal lining using CRA is some-times used. Separation of gases followed by compression increases the partial pressures of carbon dioxide and hydrogen sulfide that then increases the corrosivity. Weld corrosion may also be found on pipework that contains wet condensate saturated with carbon dioxide. Internals of thin section are normally fabricated from CRAs. Water lines and water processing equipment contain lower pressures and materials selection may allow the use of plastics. Specific concerns are 'dead legs,' areas of unused pipework that do not receive corrosion inhibitors/biocides, galvanic corrosion from mixed metal fabrications and external crevices/under insulation areas subject to wetting. Typical plant areas at risk from corrosion damage are

given in *Corrosion Threats Handbook – Upstream Oil and Gas Production*.<sup>4</sup>

Corrosion in gas/oil separation equipment typically includes:

- uniform/general corrosion caused by carbon dioxide and hydrogen sulfide;
- pitting due to chloride containing brines and sour environments;
- hydrogen damage of susceptible steels;
- CRA internal lining, either as weld overlay or a sheet clad;
- erosion corrosion due to high velocities of produced fluids at elbows and bends;
- water drop-out at low spots in low velocity regions;
- areas at the bottom of vessels that collect debris (under deposit corrosion, pitting and SRB contamination);
- microbiologically induced corrosion;
- weldment corrosion.

Corrosion mitigation includes:

- selection of ‘fit-for-purpose’ steels/CRA’s and weldments;
- use of coatings for both internal and external corrosion control;
- CP for water immersed vessel internals;
- inspection for corrosion damage;
- monitoring of CP systems;
- use of chemical treatments:
  - corrosion inhibitors
  - scale control
  - demulsifiers
  - biocides;
- on-line monitoring to identify changes and control chemical treating.

#### 4.41.1.4 Industry Drivers and Changes

Oil and gas production has derived significant economic benefits over the past 25 years from the use of asset management strategies that have been a major industry driver in eras of rising demand and fluctuating prices with operations in more severe environments, often with squeezed budgets. The asset manager in an organization essentially fulfils the traditional role of a process site managing director in balancing the requirements of stakeholders to achieve overall benefit. Asset managers have budget decision-making responsibility for resources and services to achieve defined objectives. Multi-disciplined teams are tasked with improvement of

performance, optimization of costs and minimization of risks. This asset-centered approach has increasingly replaced traditional activity-centered groups and organizations based on functions such as design, engineering, production, operations, maintenance, and materials/purchasing, each with individual budgets. Client ‘assets’ now fund technology developments with contributions from the design, SHE, IT and financial specialists from both in-house, central, shared sources and external providers. Delivery of services such as corrosion mitigation requires development of strategic models that may well include input from both in-house and third party specialists. Provision of improved quality and value is what counts rather than whether the service provider is in-house or a contractor. Asset strategies and objectives are typically encompassed in the Asset Management Policy that cascades down into local asset business goals with intentions converted into plans and actions.<sup>5</sup>

Developments in asset management cannot be ignored in the delivery of corrosion management services and will continue to drive technical and management changes. In this context, the definition first adopted in the mid-90s is still appropriate:

***Corrosion Management** is that part of the overall asset management system that is concerned with development, implementation, review and maintenance of the corrosion policy.*<sup>6</sup>

*A **corrosion policy** includes establishment of organizational structures with defined responsibilities, reporting routes, practices, procedures, processes and resources. This requires the demonstration of responsibility and accountability for corrosion performance, managing risks, decreasing costs, controlling compliance and motivating personnel.*

A written corrosion policy, agreed by senior personnel, defines the corrosion mitigation objectives and provides a focus for various interdisciplinary and multidepartmental inputs and control of operational, day-to-day activities. Most corrosion related activities are undertaken by asset management team members with limited training in corrosion mitigation and difficulties arise from an industry shortage of experienced corrosion engineers.

Major changes during the 90s centered on safety and environmental issues following the Piper Alpha Report<sup>7</sup> and a number of high-profile oil leaks. Industry centered documentation has focused on engineering/safety procedures to identify failure modes likely to affect integrity and includes the *US Pipeline Safety Act*<sup>8</sup> with emphasis on risk management and cost benefit, *API 580 Risk-Based Inspection*<sup>9</sup> plus the

accompanying resource document *API 581*<sup>10</sup> and *DnV RP G101 Risk Based Inspection of Offshore Topsides Static Mechanical Equipment*.<sup>11</sup> UK oil and gas regulations mirror EU requirements such that assets require development of a safety case,<sup>12</sup> that continues into design and construction.<sup>13</sup> This general risk-based approach continued in the '*Pipeline Standard*',<sup>14</sup> control of major hazard sites<sup>15</sup> and pressure systems.<sup>16</sup>

A framework for management process employed by the UK HSE<sup>17</sup> identifies six basic steps:

1. policy;
2. organizing;
3. planning and implementation;
4. measuring performance;
5. reviewing performance;
6. auditing.

The Norwegian regulatory authorities have adopted similar requirements. For example, contractors working for offshore operators are subjected to a SHE evaluation<sup>18</sup> where the system elements addressed include:

1. leadership and commitment;
2. policy and strategic objectives;
3. organization, resources and documentation;
4. evaluation and risk management;
5. planning and procedures;
6. implementation and monitoring;
7. auditing and reviewing.

A matrix is also used to address consequence versus increasing probability that classifies activities into three categories – (low) 'manage for continuous improvement,' (medium) 'incorporate risk reduction methods' and (high) 'intolerable.' Similar requirements are found in the ISO standard for management of environmental issues.<sup>19</sup>

A general acceptance in industry of a risk-based approach, particularly RBI, by most international organizations means that information from benchmark standards has been incorporated into in-house guidelines as part of the input into industry changes. However, risk management is only one tool employed to mitigate corrosion and, for example, adoption of a risk-based inspection system must be backed up with *management of change procedures* and *end of life strategies*.

In many countries, there has also been a cultural shift from a rules-based regulatory system to a principles-based system with emphasis on defined objectives (i.e., *framework rules with guidelines – How it must be managed by first identifying hazards and risks and then prioritize actions accordingly*) rather than traditional/prescriptive rules

based practice (i.e., *detailed rules and regulations – Defines what must be done, i.e., prescriptive, not always appropriate but do it anyway*). This change in emphasis is also reflected in the development of recent EN, ISO, and NACE standards for corrosion control such as materials for sour service,<sup>20</sup> CP and protective coatings that provide outline guidance for experienced engineers but should not be used on their own for certification purposes. In principle, the implementation of these changes in an organization and their implication for the management of corrosion mitigation may be summarized by the following steps:

1. hazard identification;
2. assessment of associated risks;
3. consider alternative ways of managing the risks;
4. conduct a cost benefit evaluation of alternative risk management options;
5. decide which option(s) to select.

In practice, corrosion related incidents/accidents still occur as shown by the South Humberside Refinery explosion/fire<sup>21</sup> and the recent Alaska pipeline leakage,<sup>22</sup> that highlight an underlying organizational concern in relation to what appear to be human errors. Management of SHE hazards, and by inference corrosion risks, can be visualized as concentric defensive barriers designed to prevent failures and catastrophic incidents by containment of hazards and limitation of their effect.

John Reason<sup>23</sup> described such barriers as either physical (hard) or procedural (soft) but each barrier has weaknesses/holes (the *Swiss Cheese Model* as described in **Chapter 4.30, Corrosion Management Overview** in this book). Holes may be caused by active failures, such as unsafe actions, and latent conditions that are an inevitable feature of organizational life. The rare conjunction of a set of holes in successive defenses, allowing hazards to come into damaging contact with people and assets (the accident trajectory) is a necessary condition for an organizational accident. Unsafe actions are errors or violations that have an immediate effect on a system, usually a direct accident at the individual level. Reason also considered *latent conditions* as arising from strategic/top-level decisions made by regulators, designers, manufacturers and managers that may be present for many years, and include poor design, gaps in supervision, undetected manufacturing defects, maintenance failures, unworkable procedures and training shortfalls. Latent conditions promote the likelihood of active failures by the creation of local factors that promote errors and violations and aggravate the consequences of unsafe acts and their effects

on a system's defenses, barriers, and safeguards, as indicated by the refinery fire and pipeline leak examples cited earlier.

The cultural shift toward principles-based legislation and industry ISO standards with an emphasis on a risk-based approach for assessment and mitigation is aimed at overcoming engineering shortfalls associated with latent conditions. This approach is also seen in hazard and operability studies (HAZOPS), technical safety audits (TSA), reliability and maintainability studies (RAMS), the control and use of databases, and the application of decision support systems that are essentially engineering applications to the control of hazards. However, the wider organizational approach proposed by Reason views human errors more as consequences than causes and as such symptomatic of latent conditions in the management system that adversely affect integrity defenses. The organizational model has therefore some similarities to TQM, that is, it uses continuous assessment to reform a system, but also combines quality-determining and safety-related factors. This organizational model approach also has many of the attributes of crisis management.

This resume highlights some relevant management philosophies on the basis of which corrosion management systems should be organized and operated. Successful management of corrosion is often achieved by being asset specific and is dependant on factors such as the design, life cycle stage, process conditions, operational history and organizational culture. There are however some basic and common requirements for management systems as first outlined in 1999<sup>6</sup> and 2001<sup>2</sup> to address continuing concerns of hydrocarbon emissions from offshore processing facilities. The aim was to develop a template based on the UK regulatory authority's approach to safety management<sup>17</sup> and encourage the industry to adopt a common approach to the assessment of corrosion management systems already in place. This has been encompassed and extended in *Guidance for Corrosion Management in Oil and Gas Production and Processing* published in 2008,<sup>3</sup> a document considered *normative* for UK operators.

The document refers to the *barrier* concept to corrosion risk management without any details, but in particular highlights the importance of *key performance indicators* (KPIs) to assess the various stages and activities of the management process and provides an extensive checklist for the assessment of corrosion management. In general, the use of performance measurement/KPIs is normal practice in most quality and

safety systems and these provide a basis for planning and measuring achievement. The setting of agreed performance criteria is crucial for the effective implementation of policies, checks on the performance of management systems and individual, day-to-day actions that are judged against acceptable criteria defined by in-house standards and/or industry benchmarks. Failure to achieve a performance standard may indicate latent conditions within a management system but should also trigger a review to identify reasons for the under-performance of the system.

#### 4.41.2 Management of Corrosion

Corrosion is a risk to both structures and production processes and as such should be treated within a risk management framework with corrosion mitigation addressed early in the project and not considered as a series of procedures introduced at a later stage. As with safety and environmental management it is a live, continuous process that starts during the concept and grows and is modified throughout the project. Management of corrosion is also a multidisciplinary team effort with input from various in-house personnel, contractors, specialists, and groups, including exploration, design, construction, operation and maintenance, as well as materials specialists and corrosion engineers. The composition and size of the 'corrosion team' and its relationship with the 'integrity team' will depend on the project stage and the asset management boundaries. Equipment integrity is a key issue from an asset management perspective and much of the equipment damage sustained throughout a project is corrosion related. For example, corrosion produces sludges (detached mill scale/corrosion products/deposits), which affect operations resulting in significant chemical treatment costs and expensive downtime for cleaning and maintenance. Secondary risks also arise with corrosion mitigation strategies such as risk-based inspection that have as their basis a rate of deterioration based on the use of cost-effective corrosion inhibitors, in which case failure of the inhibition process has implications for integrity trending.

In principle, corrosion mitigation should be an easy task, the major tactics are well established and summarized as follows:

1. **Materials selection** – carbon steels/low-alloy steel (usual to include a corrosion allowance during design), CRAs (stainless steel, nickel alloys, titanium), nonmetallic materials (polymers, glass reinforced plastic (GRP), elastomers, ceramics).

2. **Chemical treatments** – typically corrosion inhibitors, biocides and scale control chemicals but packages also include surfactants and antifoaming chemicals. Treatment may include the use of glycol to control hydrate formation combined with pH control to lower corrosion in WG lines.
3. **Use of coatings** – metallic, nonmetallic, and organic/paints, used in external and internal environments. Major factors are cost, availability, ease of surface preparation, application, and life expectancy. It is important to ensure adequate inspection of field applications.
4. **CP** – applied to immersed and buried structures, jetties, pipelines, tanks and concrete and inside water containing vessels, separators, tanks, and the water boxes of heat exchangers.
5. **Process and environmental control** – modification of moisture/humidity levels, lowering of oxygen concentrations and changes of throughput and decreases in flow and/or heat transfer rate.
6. **Design** – use of codes/standards to produce specifications and drawings. During the detailing phase, assessment of factors associated with stress, shape, compatibility and surface condition, for example, eliminate stress raisers, crevices and consider increased wall thickness on some bends.
7. **Inspection and monitoring** – trending of deterioration rates, chemical dosages and changes in process chemistries.

The first six options seen earlier are corrosion control methods that are used either singly or in combination, the choice depending on the specific application. In practice the difficulty is ensuring that long-term strategies are adopted and operational day-to-day activities are conducted effectively and efficiently.

Management of corrosion is an interactive process comprising a series of steps that aim to ensure corrosion risk mitigation procedures are applied cost effectively, commensurate with safety, health and environmental requirements. Figure 2 shows typical steps in a corrosion mitigation process based on those presented in the management of project risks.<sup>24</sup> The inputs are corrosion and SHE issues and the outputs are cost-effective corrosion mitigation, that is able to provide integrity and environmental assurance for the asset, and a continuously improving management system that is able to respond to both changing technical and worldwide economic conditions. In the UK, it would also meet the requirements for the review and audit of management systems conducted as part of a HSE assessment.

The steps are summarized as:

1. **Aims/objectives/policies.** An initial step in developing a corrosion management system is to define the aims and objectives of the corrosion input to a project. These then form the basis of the corrosion policy/strategy.
2. **Individuals/teams/organizations.** Identification of individuals and teams with ownership of corrosion management processes also helps to define roles, responsibilities and accountabilities of managers, staff and contracted bodies concerned with corrosion issues.
3. **Corrosion risk evaluations and assessment of mitigation options.** These are fundamental steps conducted throughout project life as conditions and the facility operational requirements and procedures change. The study would typically employ information as found in industry corrosion rate models<sup>25–27</sup> and guidance, including probabilistic assessments as in DnV RP G101<sup>11</sup> and API 581.<sup>10</sup> Evaluation of corrosion mitigation options, including their relative life cycle costs and required monitoring and inspection, is a basic step. The cost of preferred options must be compared using net present value/discounting procedures to obtain estimates of project life cycle costs. A useful assessment tool in the decision-making process is probabilistic analysis that enables various scenarios to be displayed as S-curves of anticipated life versus time.<sup>28,29</sup>
4. **Corrosion risk treatment planning and implementation.** These are vital to ensure that strategic, tactical, and operational/day-to-day activities designed to mitigate corrosion are employed effectively. The planning and implementation of the risk treatment process include strategic activities to meet optimal life cycle costs, SHE and other mandatory requirements, corporate corrosion practice and integrity requirements, and business concerns including development of condition-based maintenance and equipment reliability/uptime needs. The planning also includes assessment and development of chemical treating, inspection and maintenance specifications and protocols.
5. **Database development and maintenance.** The requirement for suitable databases for the storage of system documentation, the equipment design and as-constructed diagrams, commissioning information and field data generated during operation, inspection, and maintenance is given for any corrosion management system to have a chance of success. Corrosion mitigation and management

**Figure 2** Basic steps in a corrosion management system.

often falls behind other disciplines in the management and use of data, for example, compared with predictive maintenance and energy control of processing in some industry sectors. An effective management tool is a transparent database that correlates field data to provide a regular weekly/monthly breakdown of corrosion mitigation costs.

6. **Informed decisions and actions.** These are key processes; many management systems fail because of a lack of a clear decision-making step even though adequate protocols and procedures are in place. Informed decisions are based on adequate data to instigate corrective actions from investigative studies, the issuing and following up of warnings or even shut down actions when required. Operational, day-to-day actions include the rescheduling of inspections, changes to chemical treating or CP levels and predictive maintenance work or recoating that involve other teams. Recommendations must

either be followed up or rejected in a positive manner on the basis of other acceptable factors but not on a default 'do nothing' basis.

7. **Performance measurement of the management system.** Regular checks on the operating system should be conducted against agreed predetermined criteria – the performance standards or KPIs.
8. **Regular reviews.** These are normal in-house checks of overall corrosion management system performance. They ensure that management procedures and processes are consistent with any changing business plans, changing production requirements and changing legislation.
9. **Periodic audits.** Management and monitoring system audits provide evidence that the corrosion management system is efficient, effective, and reliable, and that processes and procedures are being implemented in accordance with agreed procedures. Regulations typically require owners to

ensure that adequate arrangements are established for audit report making. Any dynamic corrosion mitigation process is also reliant for acceptable or improved performance on feedback from continuous, daily checks, regular reviews and scheduled audits to modify or improve the various processing steps. These require the development and use of performance indicators and form a key part of control of the corrosion management process. The use of KPIs is normal practice in most quality or safety systems and examples in corrosion management can be found in various publications.<sup>2,3,30</sup> They can be applied at various management levels and the aim is to ensure that the management system is operating effectively so that the required actions are carried out as scheduled and appropriate decisions are made on noncompliance.

Any management system relies on feedback for review and audit of the processes within the various steps. As shown in **Figure 2** the emphasis is on assessment of the management process, first by regular/daily/weekly/monthly use of appropriate performance indicators with the review (quarterly/half yearly/yearly) and audit processes (every few years) used to not only identify areas of activity that are conforming to previously agreed criteria but also those areas needing improvement.

The left-hand output in **Figure 2** (Effective Corrosion Mitigation) has usually been the major concern of corrosion teams, especially with regards to the impact on reliable operation and asset integrity. Effective corrosion management encompasses other issues as indicated by the feedback needed for review and audits. Hence, there are two outputs from modern corrosion management process: effective corrosion mitigation (as before) and also continuous improvement in performance (top right output in **Figure 2**). That is business related and safety, health and environmental outcomes, such as increased throughput at lower costs, less hazards from corrosion, fouling, fracture, wear, and better control over asset integrity with less leakages.

### 4.41.3 Front End Engineering Design (FEED)

#### 4.41.3.1 Introduction

FEED is the process for conceptual development of process industry projects and is sometimes referred to as Front-End Loading (FEL) or Pre-Project

Planning (PPP). FEED covers robust planning and design early (the 'front end') in a project's life-cycle at a time when the ability to influence changes in design is relatively high and the cost to make those changes is relatively low, as described in the chapter on design in this book. The extra time and cost to make changes in the early stages of a project are minor compared with the costs and effort required to make changes at a later stage of the project. The influence of design stage decisions on life cycle costs is illustrated in the chapter on economics in this book.

For the oil and gas industry the FEED process is often split into pre-FEED and FEED. In pre-FEED the basic definitions of the project are identified that will cover material and energy balance, and basic economic evaluations. The basis of design is the data available on the likely produced fluid compositions and associated information on production rates, water cuts, etc. plus any specified requirements of the proponent. The main activities within the FEED itself include:

- preliminary equipment design;
- preliminary layout;
- preliminary schedule;
- preliminary and definitive budget estimate;
- identify critical/major equipment requirements;
- develop preliminary equipment specifications;
- develop project execution plan;
- preliminary 3D model;
- electrical equipment list;
- line list;
- instrument index.

Developments of new fields, especially in deeper, more aggressive conditions are pushing the boundaries of conventional carbon steel materials and hence there is an increasing focus on corrosion management at the FEED stage, where critical decisions are taken that will affect not only the fabrication/construction cost but also the long term operation and maintenance costs since these influence the corrosion mitigation strategies adopted.

Fields that have a potentially high corrosion rate are typically high-pressure, high temperature, high-CO<sub>2</sub> fields, with high levels of H<sub>2</sub>S and chloride. Development of these fields even 10–15 years ago would have been considered technically and economically prohibitive.

Traditionally, the first part of any corrosion management consideration during pre-FEED and FEED would be to determine the estimated corrosion rate for

carbon steel under the expected operating conditions throughout the expected life of the facility. This is normally carried out using industry standard models, most of which are based on the work of de Waard *et al.*<sup>25</sup> for pipelines containing CO<sub>2</sub>. There are numerous versions of these models available that have been developed and expanded by major operators, academic/research centers and consulting organizations based on the same or similar databases and the same chemical equilibria constants. The model has been extended by de Ward and Smith<sup>31</sup> to include the effect of H<sub>2</sub>S. A calculation using a standard corrosion model would be carried out to determine the likely corrosion rate of the produced fluids. Provided the estimated corrosion rates are within acceptable limits, the FEED would continue with the carbon steel option, usually with additional corrosion protection measures, as the preferred material of construction for the various components making up the development (tubulars, main flowlines, vessels) apart from specific safety critical items (down-hole completions, safety valves, choke valves, etc.).

However, because of the trend to more challenging field development it is not unusual for predicted corrosion rates of >10 or even >20 mm year<sup>-1</sup> for unprotected carbon steel to be encountered in designs, which create major challenges for traditional oil and gas production corrosion control methods. Consequently such high corrosion risk fields require a more rigorous analysis at this early stage in the field development to determine a cost-effective design from a corrosion/durability stand-point.

#### 4.41.3.2 Data Availability

A pressure/volume/temperature (PVT) report is typically the only item of data that is available at the FEED stage of a project. There are uncertainties associated with these data, particularly with regard to sampling techniques, and this has to be considered when considering suitable materials of construction.

Assessment of fluid corrosivity can be carried out by the following methods:

- theoretical calculation;
- laboratory test data;
- comparison with operational experience in a similar field.

The operational implications of any corrosion management strategy should also be considered at this stage for example

- For corrosion inhibitors:
  - Is the likely supply chain stable enough to ensure quality and delivery of any chemicals required for corrosion control?
  - Is the required inhibitor availability realistic? In particular, would an availability of 98% to 99.9% be required to achieve the necessary levels of protection?
  - Is it realistic to expect regular and routine pigging of pipelines, for cleaning purposes?
- If CRAs are to be specified:
  - Is there sufficient experience of fabrication available locally and/or within the fabrication contractor?
  - Has the likely effect of chlorides and sulfates been assessed, particularly where down-hole temperatures are high?

#### 4.41.3.2.1 Theoretical calculations

As noted earlier, the first step in the FEED is the estimate of likely corrosion rates for carbon steel under the predicted range of operating conditions. When carrying out corrosion rate predictions the following factors would normally be considered when using standard CO<sub>2</sub> models to predict corrosion rate:

- Fluid composition:
  - Propensity to hold water.
  - Scaling/wax deposition propensity.
- Water composition:
  - Chloride, bicarbonate and acetate concentration.
- Water profile over field life:
  - Water cut in early, mid and late life.
- H<sub>2</sub>S and CO<sub>2</sub> concentrations.
- Flow rates.
- Temperature:
  - Variation over field life and pipeline diameter.

The effects of flow can be complex, as described in the chapter on the effects of flow on corrosion in this book, and a number of flow models are available (such as NACE ICDA,<sup>32</sup> PIPESIMS<sup>®</sup>,<sup>33</sup> PIPEFLO<sup>®</sup>,<sup>34</sup> OLGA<sup>®</sup>,<sup>35</sup> HYSYS<sup>®</sup>,<sup>36</sup> and others) that will allow an assessment as to whether the likely flow conditions in tubulars, flowlines and pipelines are stratified, bubbly, or slugging. This then allows the likely corrosion rates to be determined for water lines and multiphase lines that have water wet walls under stratified flow. Maximum corrosion rates in CO<sub>2</sub> systems typically occur ~75 °C to 95 °C, depending on temperature, pressure and CO<sub>2</sub> content, as shown in [Figure 3](#). At higher temperatures the corrosion rates fall due to increased

**Figure 3** Typical estimated CO<sub>2</sub> corrosion rates obtained from the Norsok M506 model. Adapted from NORSOK M-506: Rev. 2, June 2005, CO<sub>2</sub> Corrosion Rate Calculation Model; Norwegian Technology Standards Institution (Norsk Søkkel) [www.standard.no/petroleum](http://www.standard.no/petroleum).

FeCO<sub>3</sub> scaling. Loss of protective scale obviously gives high local corrosion rates that can be significantly mitigated by selection of an effective inhibitor. Inhibited rates will depend on the inhibitor efficiency. The pH also influences CO<sub>2</sub> corrosion rates and this observation is employed in the use of pH control of methanol/glycol (hydrate control) injected into wet gas lines.

Standard corrosion rate models do not typically assess erosion or flow-assisted localized corrosion. The Norsok model<sup>26</sup> is limited to a fluid to wall shear stress maximum of 150 Pa and the de Waard (ECE) model<sup>27</sup> is limited to below the API RP 14E erosional velocity<sup>37</sup>; which is dependent on alloy. Other studies show that the arbitrary erosional velocity determined by API RP 14E, can be very conservative, since basic hydrodynamics, which considers the shear stress of the flow across the surface, is determined, indicate that the force created by normal flow patterns is several orders of magnitude lower than that required to damage protective iron carbonate layers, and that the effect of flow appear to be the result of 'freak energy density' or energy densities perpendicular to the wall.<sup>38</sup> This ties in with observations of areas of turbulence intensity (ratio of velocity fluctuations to the average velocity) that appear to be a key parameter in erosion corrosion in flowlines and pipes.<sup>39,40</sup> High turbulence intensity also means a high fluctuating wall shear stress and high mass transfer conditions with flow separation downstream of protrusions, bends, expansions restrictions, etc. can give rise to localized areas of erosion corrosion.

Particularly useful are corrosion models that allow for the water wetting of walls<sup>41,42</sup> and enable the ability of the fluid to hold water to be incorporated, that is a function of oil density and flow rate. Generally light oils can only hold a limited amount of water before a conductive phase is formed and condensates can only hold up to 200 ppm of water. Low flow conditions (<1 m s<sup>-1</sup>) in most oil-water systems will result in water dropout. The assessment of what is essentially the emulsion tendency of the oil is not an accurate science, and therefore in some cases basic testing is applicable.<sup>43</sup> The effect of likely step change in conditions as water content changes is seen in Figure 4, where an increase from 3% to 4% results in a rapid increase in corrosion rate as water dropout occurs.<sup>44</sup>

As an alternative to assuming 'worst case' situations, the predicted or measured corrosion rate data can be expressed as graphs of probable life for different scenarios, as illustrated for a particular field development<sup>45</sup> where the options under consideration were:

- do nothing;
- wait for water breakthrough to occur;
- install monitoring facilities and chemical treatment facilities now.

Option (a) has obviously the lowest capital expenditure (CAPEX), but has the highest risk relating to repair works and/or premature abandonment of wells. Options (b) and (c) have the same CAPEX

costs, but option (b) has the advantage that the work can be delayed and/or phased to optimize expenditure, but runs the risk of unforeseen delays, which could result in unacceptable metal loss and some failures. Option (c) would be expected to provide the lowest risk option.

Baseline (uninhibited) corrosion rates for tubulars, flowlines and gathering lines were predicted to be between 0.3 and 0.9 mm year<sup>-1</sup> using standard industry models. These could be controlled by the installation of chemical treatment facilities and the injection of corrosion inhibitors. Additional parameters taken into account were:

1. time after water breakthrough before water detected;
2. time to procure chemical injection components and install (For option (c), assumed to be already in place);
3. inhibitor availability, that is, reliability of supply;
4. inhibitor efficiency, that is, effectiveness of inhibitor once applied.

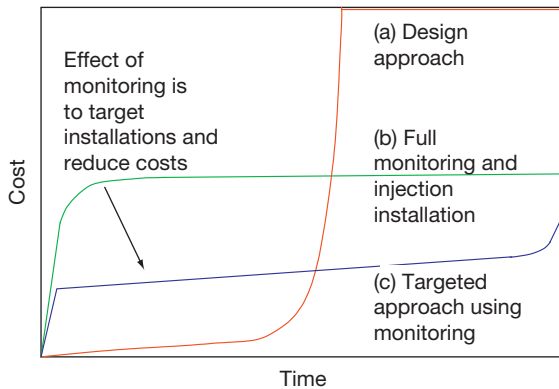

The analysis gave the results shown in **Figure 5** with the corresponding financial projections indicated in **Figure 6**, that justify the development of a mitigation and monitoring strategy for the field development.

**Figure 4** Part of a corrosion assessment for a field development showing the influence of water cut on the predicted corrosion rates. Reproduced from Moosavi, A. N.; John, D. G. In *Corrosion/2002*; NACE: Denver, CO, 2002; Paper No 02225.

**Figure 6** Cost versus time implications of different scenarios. Reproduced from John, D. G.; Stokes, P.; McIntosh, P. *Risk assessments as part of a pipeline integrity determination for subsea oil and gas pipelines*, paper 03163, presented at NACE CORROSION'2003, San Diego, CA, March 2003.

#### 4.41.3.2.2 Corrosion risk analysis (CRA)

Corrosion rate data, from models or field information, can be used to assess corrosion risk across an asset or with individual equipment items (RBI). A common approach is the use of matrices, with linear or logarithmic scales, to prioritize risks and then to focus efforts on the most influential by evaluation of options. Important aspects for design teams or asset management teams are that a formal assessment of threats/risks is conducted using preagreed 'rules' or criteria are employed to define the likelihood of corrosion, the effect of corrosion and a ranking of the severity. The assessment report provides documentation for the next steps in the mitigation/management process and demonstrates the rationale employed by the corrosion engineer and replaces for other team members what often appears to be reliance on a subjective corrosion judgment.

Risk matrices provide a simple visual way of assigning risk where the consequences and likelihood of a failure are assigned to rows and columns of a matrix. Any combination can be used, the most common being based on four or five rows and columns; however, up to 10×10 matrices have been used by some operators. A typical 4×4 risk matrix is shown in Figure 7. Using this type of risk matrix identifies items where the risk is 'extreme' (i.e., where failure is both likely and of major concern), which should have immediate action taken (e.g., change of design, material selection, change in operations, etc.) to reduce the risk to an acceptable level. Items that are 'high' or 'medium' should be monitored during operations via a combination of

**Figure 7** Example of a typical risk matrix.

inspection, corrosion monitoring and fluid sampling. However, items where the risk is identified as 'low' (i.e., where failure is both unlikely and would be of little concern) require less attention.

Data collected during operations should be fed back to enable the risk assessment to be reevaluated. While the consequence of failure is unlikely to change during operations (with some exceptions, e.g., pressure reduction), the uncertainty in the data used to assess likelihood will normally be reduced by the collection of operational data, and where justified, the likelihood of failure can be reduced (or in some cases increased) as appropriate.

It should be noted that in other publications and operational systems 'likelihood of failure' and 'probability of failure' may be used interchangeably. The authors preference is to use 'Likelihood' for qualitative and semiquantitative risk assessments, and 'Probability' for full quantitative assessments. Further details of corrosion risk assessments, and use of corrosion risk matrices are given in Chapter 4.30, Corrosion Management Overview in this book and elsewhere.<sup>3,11</sup>

#### 4.41.3.2.3 Laboratory testing

While predictive modeling as described earlier is being used increasingly as part of the preliminary assessment approach, there remains a need for laboratory tests to confirm the likely corrosion conditions that will occur. This is especially so for systems with high CO<sub>2</sub>/H<sub>2</sub>S content, where many models will predict very

high corrosion rates (often  $>20 \text{ mm year}^{-1}$ ) but where practical experience indicates that corrosion of carbon steel is negligible. For example, a review was carried out of production facilities in Oman<sup>43</sup> where performance in service of carbon steel components was compared with laboratory tests,<sup>46</sup> which showed that a stable FeS film is formed, giving *natural* corrosion rates (i.e., in the absence of corrosion inhibitor and not taking into account any oil wetting) of:

- gas phase  $0.02\text{--}0.05 \text{ mm year}^{-1}$ ;
- liquid phase  $0.08\text{--}0.18 \text{ mm year}^{-1}$ .

As part of the study, the water cut point at which a water/oil emulsion will release the water, thus switching from being an oil-wetting to a water-wetting mixture, was measured by determining the change in polarization resistance. The results for two different crude types showed that with one up to 20% water addition was required to affect the polarization resistance, while only 5% water addition was required for the other crude to have the same effect. These results were consistent with standard oil–water emulsion stability tests, ASTM D1401,<sup>47</sup> where emulsion stability is determined by the time required for the emulsion to separate after controlled agitation. The emulsion stability tests showed that the first crude formed a stable emulsion (stable for more than 24 h), while emulsions formed with the second crude broke down within 2 min. Data that are consistent with published experience.<sup>41,42</sup>

This evidence that the combination of a stable FeS scale formation and absence of a conductive phase in low water cut conditions provides acceptable levels of natural protection, making the use of carbon steel was viable, despite high theoretical corrosion rates, which is also supported by field experience led one operator to now require laboratory testing be carried out to assess the corrosivity of the fluids, and in particular the degree to which light crudes/condensates to hold water, for all future projects and not to solely rely on predictive rates.<sup>43</sup>

Even in areas where natural protective scales are not formed, where predicted field conditions are aggressive, such that carbon steel with corrosion inhibition with an efficacy of  $>95\text{--}98\%$  is required and specified, it is often appropriate to carry out chemical screening tests at the FEED stage to ensure that a product is available in the market for the field conditions at a reasonable cost that can achieve the required corrosion efficacy for the life of the field.

Another key aspect that also has to be considered in any laboratory test program relates to presence of

organic acids, and in particular, acetates in the oil, as described by Hedges.<sup>48</sup>

#### 4.41.3.3 Procurement, Installation, and Operational Practicalities

Construction of oil and gas facilities worldwide comes up against a number of issues that differ from region to region and product to product including availability in specified thicknesses or line pipe grades, fitness for service (FFS) in sour service ISO 15156, shipping and storage costs as well as issues associated with basic materials selection considerations, i.e.:

- functional requirements;
- performance specification;
- design/redesign configuration;
- total life cycle in design;
- product availability and durability;
- inspection and QA testing;
- handling, packaging, shipping, and storage.

Procurement of raw materials is an issue as a vast proportion of the world supply of steel for equipment fabrication and pipelines comes from mills in the Far East where, unfortunately, there have been problems ensuring that the steel quality always meet the high stringent requirements of the oil industry, including the availability of compatible fittings (although it is recognized that European and North American mills have also been found wanting with regard to material quality in some instances).

Quality Assurance (QA) of manufacture must be considered at the FEED stage of a project. An understanding of these factors is essential for cost-effective materials selection and corrosion management during operations. The tolerances on standards and codes may be affected due to availability of source material. In some cases this can be an advantage from a corrosion perspective as often the higher specification of materials is purchased on grounds of availability. The cost of materials will vary from mill to mill and transport costs should also be considered during the lifecycle cost estimate.

The consideration of government legislation in terms of import and export of goods may also have to be considered. The level of tax imposed and the requirement for certificates of origin are both dependant on the local government regulations and are liable to change.

For example, if the government of a developing country requires the inspection of all 'key' components

that are imported to be carried out by a government appointed agency at the operator's cost, then the definition of 'key' components could be crucial to the viability of the project. If, for example, 'key' was defined as any pipeline, valve or fitting over 4" in diameter, that would have a major impact on the project economics. However if, through negotiation, key components are reclassified as those that are 6" diameter and above then the imposed QA cost can be significantly reduced and this will influence the life cycle cost analysis.

Fabrication of topside modules are often carried out in a completely different location to the pipelines and interlinking pipework and therefore compatibility of materials (selected by different design teams/fabricators) must also be considered. The supply of piping specifications, codes, schedules, etc. should be available irrespective of the manufacturing route, and the language of documentation should be clearly specified.

Consideration should be given to the locally available resource for fabrication of equipment. Handling and welding procedures for CRAs require much more stringent controls and may also require pre-qualification testing in H<sub>2</sub>S containing fluids, than normally employed for carbon steel products and incorrect procedures can lead to failures during commissioning and operations.

Specification of chemical injection facilities should be clearly understood at the FEED stage. If a high level of chemical availability is required, the quality of equipment, redundancy and availability of spares should be considered, particularly with high-risk inhibition systems.<sup>30</sup> The local supply chain should be investigated to ensure that, if required, a continuous supply of product is feasible.

For example, in many remote parts of Russia the present chemical injection philosophy is to periodically top up gravity fed chemical storage systems to feed into well head systems. However, during the summer periods, wellpads that are situated in swamp areas become inaccessible, resulting in no delivery of chemical and hence lack of protection. Consequently for critical well heads consideration is given to providing continuous injection via large capacity well head storage tanks that only require restocking twice a year (i.e., when reliable access to the wellpad is available). Similarly for small scale offshore applications, where well head platforms are unmanned, an umbilical supplying chemical to the platform may be required. Where the platform is manned or easily accessible, regular top up and monitoring of the offshore tanks can be carried out; however, in these cases local storage

facilities should be sized to ensure continuing availability of chemical if supply boats are delayed due to bad weather. Temperature differences between winter and summer operation in many desert areas mean that viscosity changes in inhibitor packages result in a change of injection pump operation and hence a change in dosage and/or selecting injection pumping facility that is reliable in varying conditions.

Another area that should be considered at the FEED stage is for necessary inspection and monitoring requirement to achieve the longer term objectives/corrosion strategies, including the type and location of appropriate monitoring devices. There are a wide number of techniques (corrosion coupons, electrical resistance (ER), linear polarization resistance (LPR), etc. as described in **Chapter 4.36, Corrosion Monitoring and Inspection** in this book and also later in this chapter) and commercially available products that assess the condition of equipment or the corrosivity, chemistry or biochemistry of the fluids. Consideration should be given to the technical and economic feasibility of their use and the FEED should not assume that these will be specified at a later design stage. In particular, it must be noted that the use of insert probes or coupons is now subject to more stringent control in many areas, including the required use of a double block system. The use of instrumented spool pieces, permanently installed devices such as UT mats, or similar systems, as shown in **Figure 8**, are increasingly being adopted as standard practice. Consideration should also be given to having at least two or three complementary methods to ensure reliance of field data.

Retrieval of data from corrosion monitoring devices should also be considered. For remote facilities, automated systems may be required, while for easily accessible systems where labor is readily available, daily retrieval of data is normally considered adequate, except for very high-risk systems where inhibitor availability is more than 98%.

A preliminary assessment of design requirements for the specification of external corrosion mitigation should also be undertaken to identify any specific requirements. In some cases it may be appropriate for a design for the CP system to be carried out for pipelines, and structures at the FEED stage, along with consideration of coatings for external protection. There is also a need to identify the supply of materials and local training requirements to ensure a system is designed, delivered and maintained to meet the long term objectives in a straightforward and easy-to-implement manner.

**Figure 8** Examples of spool pieces and permanently installed devices.

Key questions that need to be considered for materials and monitoring equipment are whether the supplier has local representation in the region where the system is going to be installed if servicing is required and whether suppliers have the experience of supplying material and equipment to similar fields.

#### 4.41.4 Design Stage

At the design stage of the project the detail drawings and specifications are prepared for construction and this is the opportunity to get it right or, unfortunately as still happens, to really get it wrong! Modifications beyond the design stage are costly and inconvenient.

For example, in a case known to the authors, an onshore field designed on the basis of using aquifer water for downhole injection suddenly found that the injection waters contained SRB, which required a change in operating philosophy with implementation of significant monitoring and biocide treating facilities.

Depending on the size of a project, the design stage may be divided into two stages of *Engineering Design* and *Detailed Design*. Corrosion related activities undertaken during the engineering design phase include:

- detailed materials selection, including the use of design codes, standards, and procedures for construction, fabrication, and assembly;
- assessment of proposed corrosion control options.

During the detailed engineering design, detailed specification and drafting of procedure are undertaken to produce the finalized design specifications and engineering details that are required for construction.

The following is an example of documents that require some level of corrosion input during the engineering design and detailed design phases of the project:

<i>Engineering design</i>	<i>Detailed design</i>
Basis of design	CP design
Material specification	Pipeline, vessels, tubulars,
External coating	valve specifications/
specification	testing
Insulation specification	Welding procedures/testing
Material selection	Corrosion monitoring
philosophy statement	designs/specifications
Corrosion monitoring	Equipment specification/
philosophy statement	inhibitor testing/data
Chemical management	management specification
philosophy statement	

#### 4.41.4.1 Documentation

##### 4.41.4.1.1 Material selection report

The material selection philosophy would normally be developed by materials specialists and should be

written into the project at the engineering design stage. It would typically contain details of materials for each system based on the fluids and operational conditions, plus details on materials specifications and properties. For example, for pipelines basic requirements would include standard dimensions, adequate strength for operational pressures, material to be identifiable and traceable, weldable under site conditions, free from defects that would cause leakage, and adequate fracture toughness to resist brittle fracture and resist propagation. Most requirements for linepipe are covered in API 5L<sup>49</sup>/ISO 3183,<sup>50</sup> but other requirements must also be specified including testing for weldability, fracture toughness tests, sour service tests to ISO 15156/NACE MR0175<sup>20</sup> (including testing for SSCC susceptibility to ASTM G39<sup>51</sup> and NACE TM0177<sup>52</sup>) restrictions on manufacturing process, limitations on chemical composition, element ranges, wall tolerances, and marking requirements. Budget costs are an output from the materials selection process.

One approach typically adopted in many projects would be the development of material selection diagrams (MSDs), that are based on the process flow diagrams (PFDs). They show the generic materials type, applicable corrosion allowance, internal coating requirements, and any other corrosion control requirement for pipelines, vessels, and piping, for example, as shown in [Figure 9](#).

At the detailed design stage the detailed materials specifications would then be developed with reference to appropriate standards. Piping schedules are produced that detail the appropriate material grade, wall thickness, operating pressure and temperature for each specific service in addition to insulation and welding specification and post weld heat treatment (PWHT) requirements. This information forms the basis of the line identifier on the process and instrument diagrams (P&IDs).

#### 4.41.4.1.2 Corrosion management philosophy

This document should contain high level details of the monitoring and mitigation measures that are required for the installation, plus important information that needs to be carried forward to detailing, specifications, fabrication and construction and operation, for example:

- injection of corrosion inhibitor to mitigate CO<sub>2</sub> pitting/general corrosion and H<sub>2</sub>S pitting corrosion;
- injection of biocide to mitigate MIC corrosion;

- injection scale control chemicals;
- injection of chemicals for pH/hydrate control;
- deoxygenation/treatment of injection water;
- CP of pipelines, structures, internals of vessel and tanks;
- corrosion/erosion (sand) monitoring;
- specification of pipe internals to remove mill scale during external blasting for coating application, which minimizes sludge formation during the first few years of operation as CO<sub>2</sub>/H<sub>2</sub>S corrosion products replace air formed films;
- routine cleaning of pipelines using cleaning pigs;
- routine flushing of sand from vessels and procedures for removing sand deposits from lines/manifolds following sand breakout in a well.

This will enable the equipment to be designed to deliver these various requirements.

#### 4.41.4.1.3 Chemical injection systems

Where chemical injection of corrosion inhibitors, biocides, scale inhibitors, emulsifiers/deemulsifiers, etc. is required it is important that the injection location and injection facilities are correctly identified. The injection must take place sufficiently far upstream of where the chemical is expected to provide benefit to ensure adequate mixing. Typically, this mixing distance will be defined as at least 2 m or 10 pipe diameters upstream. Where more than one chemical is required at nominally the same point they should be injected separately and not via the same injection point to avoid the risk of clogging. The injection nozzle should also be designed to provide the optimum distribution into the stream.

The method of injection, that is, the use of mechanical or electrical pumps, and local storage also have to be taken into account in relation to factors such as protection from solar heating, the use of plastic or stainless steel tanks, etc. In the concentrated form corrosion inhibitors and other chemicals can be very corrosive and/or toxic and hence suitable precautions, including the use of austenitic stainless steels for injection equipment and lines, will be needed to prevent leakage.

The pumps will also need to be sized so that sufficient chemicals can be injected into the stream to ensure the necessary dosage levels. Most corrosion inhibitors are formulated to be typically present at levels of 10–20 ppm (in the range 5–100 ppm) and, depending on the production rates, the actual amount of chemical injected could range from 2 dm<sup>3</sup> day<sup>-1</sup> for production facilities of 167 m<sup>3</sup> day<sup>-1</sup> (1000 bpd)

**Figure 9** Example of material selection diagram (taken from NACE SP0407). Reproduced from NACE Standard Practice SP0407-2007 'Format, Content and Guidelines for Developing a Materials Selection Diagram'.

up to  $30 \text{ dm}^3 \text{ day}^{-1}$  for production of  $1670 \text{ m}^3 \text{ day}^{-1}$  (10 000 bpd). A description on the use of inhibitors in oil and gas operations are given in **Chapter 4.26, Chemical Treating in Oil and Gas Production** in this book and elsewhere.<sup>30</sup>

#### 4.41.4.1.4 CP systems

The majority of CP systems will be aimed at the external protection of offshore production facilities such as fixed platforms, floating platforms and FPSOs, onshore and offshore pipelines, and onshore storage tank bottoms. However, CP can also be applied to the internals of oil and gas process equipment, including separators, filters, heat exchanger water boxes and storage tanks.

The selection decision for pipelines and storage tanks at the design stage will be between the use of galvanic anodes and/or impressed current systems, and the extent or otherwise that different components are electrically isolated or deliberately bonded together. Note that CP will protect against crevice corrosion if applied as soon as the component is immersed but, will not necessarily protect crevices after the corrosion has initiated. For offshore applications, and in particular subsea developments, the compatibility of CP systems required for carbon steel pipelines and other structures also has to be assessed, specifically for the effects of over protection on either high strength carbon steel components or components fabricated from other materials such as duplex stainless steels and titanium. While CRAs may not require external CP, they will receive it, because they are connected to carbon steel pipelines that have CP applied, and this has led to failures of subsea manifolds in the past.<sup>53</sup>

Internal CP can also be applied to process equipment and the main concerns relate to the low pH/elevated temperatures in the process, which in turn leads to higher current demand and low anode performance and hence more challenging CP design. Most internal CP systems are galvanic<sup>54,55</sup>; however, impressed current CP systems have also been installed.<sup>56</sup>

If internal CP is to be incorporated it is important that ease of anode installation/replacement is taken into account as part of the overall design. Methods for determining performance are also more complex, and include the use of ER probes.

#### 4.41.4.2 Engineering Considerations

##### 4.41.4.2.1 Minimizing corrosion threats

Variations in pipeline and pipework geometry, such as the presence of dead-legs and low points, create areas

where water and debris can settle and accelerate a number of different corrosion threats, including  $\text{CO}_2$  corrosion, under deposit corrosion and microbial corrosion, as illustrated in **Figure 10**. Similarly, sections of pipeline that cannot be pigged increase the chance of build-up of deposits. While low points and dead legs cannot be fully eliminated in any design, they can be minimized. The awareness of corrosion should be raised with the piping designers at the design stage of a project and, where possible, a review of the piping design should be carried out to challenge any excessive use deadlegs and low points.

##### 4.41.4.2.2 Corrosion allowances

Most carbon-steel components selected for use in oil and gas facilities will incorporate a corrosion allowance. The wall thickness for the component (pipeline, pipework, vessel, tank, etc.) will be increased above the minimum allowable wall thickness as determined by the appropriate design code, to allow for metal loss due to corrosion or erosion. This is separate from the inclusion of a fabrication tolerance for the component.

The corrosion allowance will be selected based on the expected corrosion rate that will occur with the planned corrosion control procedures in place and allowing for the design life of the facility. The inhibitor availability concept provides the procedure that should be used in practice.

During operation, provided that the actual metal loss, as determined by inspection and trend monitoring according to API 570,<sup>57</sup> API 580,<sup>10</sup> or other RBI system, is less than the corrosion allowance then the component will be operating within the design code requirements and is considered fit for service. Only when the actual or estimated metal loss exceeds the corrosion allowance would a more detailed assessment as to the continued fitness for service (FFS) be required (see **Section 4.41.6.9** later in this chapter).

Typically, corrosion allowance would be 2 or 3 mm, and while most projects try and limit corrosion allowance to 6 or 8 mm, in some cases a corrosion allowance of up to 12 mm have been considered, especially where there is a risk that the corrosion control program may not be fully effective. However, other projects choose not to include any corrosion allowance, normally this is when there is a high confidence in the effectiveness of the corrosion control program (for example for commercial quality dry gas pipelines).

##### 4.41.4.2.3 Inaccessible pipework

While some piping, especially for offshore installation, will not be easily accessible, it is important to consider that corrosion monitoring equipment needs

**Figure 10** Schematic of 'dead-legs,' from the Energy Institute 'Guidance for corrosion management in oil and gas production and processing.' Reproduced from *Guidance for Corrosion Management in Oil and Gas Production and Processing*; Energy Institute: London, May 2008. ISBN 978 0 85293 497 5.

to be accessed by retrieval tools and that the external surface of piping will need to be inspected.

For subsea pipelines, direct access is almost impossible and therefore the design should be robust enough to deliver a 'fit and forget' solution. There should be a high level of confidence in any monitoring equipment that is to be located in inaccessible locations.

#### 4.41.4.2.4 Insulation

A major problem with external corrosion of oil and gas production facilities is corrosion under insulation (CUI), where excessive corrosion and/or SCC can occur where water (rain water, seawater, deluge water, etc.) enters the insulation. In many cases, the insulation is necessary for process control and hence steps need to be taken to ensure that that system is correctly designed to reduce the threat of water ingress and also to minimize any subsequent corrosion by use of protective coatings on the metal piping.<sup>58,59</sup> Where insulation is not necessary, for example, when solely used for personnel protection, it should be removed and alternative methods to prevent harm, such as the use of open mesh guards, applied.

#### 4.41.4.2.5 Pigging facilities

The installation and design of temporary or permanent pigging facilities should be considered and will

be dependant on the expected frequency of pigging and the availability of labor. Consideration should be given at the design stage to the requirement to pig individual pipelines, which can impact on detailed materials selection philosophy. Normally unmanned installation (NUI's) that require regular launching of cleaning pigs to protect the export pipeline will require a robust automated launching system that is capable of storing the number of cleaning pigs that are required between visits to the facility.

In the case of an onshore facility with an extensive pipeline and flowline network that has the need to run cleaning pigs on a monthly basis in the flowlines, the installation of permanent pigging facilities at each wellhead may be considered prohibitively expensive and the design of mobile pigging facilities for each region of the field may be considered. The number of temporary pig launchers needs to be balanced with the number of teams that will be available to carry out the pig launching and receiving activities. Alternatively the pipeline network can be designed with pigging loops to enable launch and reception to be carried out in similar locations.

It should be recognized that one of the major hurdles for many existing pipelines world wide are pipelines that are not piggable, either because the lines include bends that are too tight or more often

because the internal diameter (bore) of the pipeline is not constant, such that pigs (whether used for cleaning or inspection) cannot travel along the line reliably. In general the less a pipeline is cleaned the higher the possible corrosion threat.

#### 4.41.4.3 Design of Data Management Systems

At the design stage, the type of data management system that is required for the facility should be considered<sup>60</sup> and the selected system will normally be set up during the construction phase in order to input inspection information such as 'as built' wall thickness measurements. The choice of corrosion management system may influence, or be influenced by, the corrosion monitoring and materials of construction. If the corrosion monitoring is linked into an online measurement system (e.g., PI, SCADA) then a real time corrosion data management system can be used.<sup>61</sup> If a high level of manual inspection is to be carried out then a comprehensive inspection management database should be considered, particularly if RBI is to be adopted.

Methods and procedures for all activities will be required, including specifications, procurement of materials, testing, fabrication and welding, coatings, CP equipment applications, corrosion monitoring and inspection instrumentation, field data collection and analysis, required databases and means of achieving their population, specification of reporting by appropriate routes and development of corrective action procedures to be carried out when necessary.

The development and maintenance of corrosion databases, usually electronic, could include provision for storage of system documentation including facility design documents, as-constructed diagrams, commissioning information and field data during operation, inspection and maintenance. These should cover information on the basis of the design, design drawings, modifications, testing requirements and construction so that relevant information data are transferred through to the operational phase database.

The means by which field data such as visual inspections, coating surveys, hand held/permanently wired instrumentation, DCS/SCADA downloads are to be collected, analyzed, and used for trending and correlations must be agreed and specified, including post fabrication inspection data that provide the initial field data point for trending as in RBI.

An effective management tool is a transparent database that correlates field data to provide a regular

weekly/monthly breakdown of corrosion mitigation costs. Ideally, field databases should be live documents where measurements are inputted as soon as possible and analyzed/trended/correlated to provide virtually continuous management information for the corrosion team leader/supervisor. The use of a web page approach is becoming more accepted with simple traffic light schemes (red, yellow, green) providing easy to identify out-of-condition processes.

#### 4.41.4.4 Commissioning Procedures

During the detailed design phase, commission procedures should be written for each area. Procedures that have particular emphasis on corrosion are:

- commissioning procedure for chemicals management system;
- pressure testing and preservation procedure (in particular water treatment for hydrotest systems).

### 4.41.5 Fabrication, Construction, and Commissioning

#### 4.41.5.1 QA and Quality Control

An integral part of maintaining technical integrity of a new facility is to ensure that the materials selected in the FEED/Design Phase are manufactured, procured, and constructed as envisaged and in a way that they maintain their degradation resistant properties for the intended use. Normally the responsibility of ensuring that materials meet required specification will fall to the QA teams within the design project team. Their role is to ensure that the minimum compliance checks and nondestructive examination requirements are fully adhered to and that the construction materials retain their original specified properties.

A main issue that needs to be addressed during fabrication and construction is that where special properties for a material are required, in particular with respect to sour service in accordance with ISO 15156/NACE MR 0175,<sup>20</sup> they are delivered as specified. Note this should not just rely on material certificates unless supported by internationally recognized standards/quality control organizations. Many problems have arisen where materials have been supplied as being of a particular grade and in accordance with specification, only for them to be eventually discovered as being out of specification, for example, austenitic stainless steel grade SS316L (UNS S31603/EN 1.4919) piping specified, but grade SS304 (UNS 31400/EN 1.4841) supplied, or forged valves specified

as being compliant to MR 0175<sup>20</sup> found subsequently to have unacceptable hardness, resulting in cracking and failure after only a few weeks operation.<sup>62</sup>

Any deviation or other changes to the original design should only occur after review and approval by the design team and should always be fully documented and the responsible material and corrosion engineers notified in order to ensure that the relevant information is incorporated into the corrosion management manuals.

During fabrication and construction, items of equipment will be subjected to a range of routine inspection to confirm fabrication in accordance with specification and code requirements. In addition it is increasingly used to ensure that as delivered wall thickness checks (using nondestructive inspection systems, such as ultrasonic wall thickness systems) are carried out to confirm the original wall thickness prior to operations. This then becomes the baseline value used in assessing performance during ongoing operations, and eliminates the uncertainty associated with actual versus nominal wall thicknesses.

#### **4.41.5.2 Development of Integrity Management Systems**

During this phase, the integrity management systems are normally set up. This should comprise a suite of documentation that enables a structured framework for integrity management to be delivered and should cover integrity policy, strategy, codes of practice procedures, specifications, and guidelines. Some of the typical documentation required includes:

- integrity management policy and strategy;
- sand management strategy;
- corrosion management manual;
- hydrotest and preservation procedures;
- chemical management strategy;
- RBI strategy;
- corrosion monitoring manual;
- inspection procedures.

Risk assessments and the generation of RBI plans require PFDs, piping and instrumentation diagrams (P&IDs), MSDs, pipework isometric drawings, vessel data sheets and process and operations manuals to be available. Development of the integrity management system during the construction and commissioning phase enables the systems to be implemented from day one of operations. This ensures that all operational data are collected and fed back into the system.

Corrosion and materials consulting engineers typically act in an advisory capacity during the construction and commissioning phase to assist in the following activities:

- Define requirements for integrity management systems;
- Reassess design decisions related to integrity monitoring and mitigation.
- Advise on materials approvals, quality control and QA checks.

During commissioning it is important that the detailed hydrotest and preservation procedures are followed, the chemical injection packages are commissioned and the dose rates and logistics associated with chemical supply are confirmed. Vibration screening should also be carried out during commissioning of susceptible components.

Following fabrication and construction, the facilities will be tested and commission in different phases. Even at this stage, full attention to corrosion management requirements is vital, since major damage and/or problems for future operation can be created during this stage.

A significant issue relates to hydro-testing of pipelines, pipework, and vessels, which, unless carried out correctly, can lead to major problems. This includes problems associated with leaving inadequately treated hydrotest water in the line allowing oxygen corrosion or MIC due to introduction of bacteria, that can lead to severe metal loss prior to operation or, if the line is not fully cleaned and dried, can leave water in place that then allows corrosion to proceed once production starts.

Most problems associated with external corrosion of pipelines are also caused during pipe laying, either due to damage to the coating, in particular the field joints, either due to 'roller damage' for offshore or mechanical damage from slings, stones, etc. during trench placement onshore.

#### **4.41.5.3 Handover to Operations**

Following successful commissioning the fabrication and construction team will disperse. Before this occurs all historical records developed during the fabrication, construction and commissioning phase that could be useful for ongoing operational corrosion management should be handed over to the operational team responsible for ongoing corrosion management.

The extent of this information should not be underestimated (see compliance with ISO 9001: 2008<sup>63</sup>)

and the key documents and information are summarized in the following section. It should be recognized that this is not an exhaustive list, but intended to give guidance on the type of information that is not only useful for corrosion, inspection and integrity engineers during operations but identifies the means by which risk mitigation is transferred from design to operations.

Handover documents:

- Basis of design.
- Corrosion management premise.
- Material selections and peer review.
- Corrosion management manual (including preliminary inspection/monitoring plans, reporting plans, KPIs, etc.).
- RBI plan.
- PFDs marked with corrosion circuits.
- Maintenance reference plan.
- Preservation procedures.
- Hydrotest procedures.
- Chemical injection procedures.
- Piping and instrumentation diagrams (P&IDs).
- Process flow diagrams (PFDs).
- Operations manuals.
- Corrosion barriers spreadsheet.
- Process simulation/heat and mass balance data.
- Hydrotest procedure.
- Chemical dosing manuals/procedures.
- Adequate manpower, material and equipment resources need to be allocated to undertake the plan. Permanent physical facilities should be installed.
- The locations for monitoring and inspection activities should be defined.
- Procedures and instructions should include criteria of nonconformance.
- A corrosion damage reporting process should be continuously in place to capture information regarding failures that occur unconnected to the planned activity.
- A procedure should be in place to allow for opportunity based inspection, separate to the plans, of items that are not normally accessible for operational reasons.

An important point to realize in any corrosion management implementation is that *'no plan survives contact with the enemy'*<sup>64</sup> and, as a consequence, it is unlikely that all the original plans and procedures will be able to run smoothly thought the operational life of a facility. Hence, as either process conditions change (e.g., due to increase in water cut, incorporation of new production wells, changes in oil lift methods, etc.) or where unforeseen events occur (e.g., failure of chemical injection facilities) then alternative methods of detection may be required to be used and incorporated into the corrosion management 'tool kit,' either in place of, or in conjunction with, existing methods. Any new inspection and monitoring technologies should also be evaluated and considered as part of an ongoing system improvement process.

## 4.41.6 Operations Phase

### 4.41.6.1 Corrosion Management Strategy Implementation

Implementation of the corrosion management strategy involves the correct execution of the mitigation, monitoring and inspection activities that ensure the facility remains fit for purpose. Examples of these activities are corrosion rate monitoring, process monitoring and inspection, data collection, analysis, reporting and corrective action.

The requirements for implementation are:

- The strategy should be translated into practical instructions, for example, planned maintenance routines, operating instructions and work packs. There should also be a means for implementation of the strategy.
- Written procedures, work instructions and guides to performing the implementation tasks should be provided. Responsibility for implementation should be identified.

### 4.41.6.2 Routine Inspection and Monitoring

Corrosion inspection and monitoring are key activities in ensuring asset integrity and control of corrosion. It is important to monitor appropriate parameters that indicate the performance of a corrosion barrier to check whether the performance limit has been exceeded.

Monitoring can comprise inline, online and offline systems and provide rate of corrosion degradation data and information on the effectiveness and performance of the corrosion mitigation techniques (e.g., corrosion inhibition, process treatment, etc.). Analyses of the results from these systems allow steps to be taken to prevent failure, if necessary.

In-line systems are devices installed directly into the process that need to be extracted for analysis or

sampling of process fluids for analysis, for example, corrosion weight loss coupons, biostuds, fluid sampling, etc.

*Online* corrosion monitoring techniques, that is techniques that use fixed probes or sensors that can be integrated without the need to remove them from the system (insert probes or externally mounted probes), include:

- electrical resistance (ER) probes;
- linear polarization resistance (LPR) probes;
- fixed ultrasonic (UT) probes;
- acoustic emission;
- electrochemical noise;
- monitoring of process conditions;
- magnetic flux leakage (MFL) or UT in line inspection (intelligent pigging) of pipelines;
- field signature method (FSM) monitoring spools.

*Offline* techniques retrospectively identify corrosion degradation and quantify the onset and causes, and the extent and degree to which it has occurred. Offline monitoring or inspection mainly utilize the following inspection and nondestructive testing/evaluation (NDT/NDE) techniques:

- visual;
- manual/automatic ultrasonic;
- radiography;
- pulsed eddy current (PEC);
- magnetic flux leakage (MFL);
- time of flight diffraction (TOFD).

Detailed descriptions of the different inspection and monitoring systems, together with their advantages and disadvantages, are described in **Chapter 2.04, Pitting Corrosion** in this book and in various standards, technical reports and other publications.<sup>65–71</sup> New inspection and monitoring technologies should always be evaluated and considered as part of a continuous improvement process, for example, a combination of new development methods (FSM and electrochemical noise) were used successfully to identify corrosion problems in an aging sour gas system.<sup>72</sup>

Regular proactive and reactive monitoring should be undertaken to measure the degree to which the policy objectives of the corrosion management plan are being achieved. There are two measurements of success: (1) meeting the performance limits for the effectiveness of the corrosion barriers, that is, the FFP of the facility and (2) meeting the targets in terms of the effectiveness of identifying the barriers

and organizing, planning and implementation, that is, the success of the management system itself.

Routine inspection provides a key input into corrosion management activities. This is mainly aimed at nondestructive inspection to determine the wall thickness of pipelines, pipework and vessels, but also includes NDT/NDE to identify cracking or other forms of deterioration. The most common form of inspection utilizes wall thickness measurements obtained using compression ultrasonic probes (UT). Various types of UT systems are available, including simple ‘all-in-one’ probe and digital meter, digital wall thickness gauges and full screen systems, which allow measurement at points on the surface. With these units the operator manually moves the sensor around the area to locate the point with the lowest wall thickness. Fully automatic scanning systems are also available that can travel around/along the component providing a 3-D image of the wall thickness allowing clear identification of localized corrosion.

While simple digital only UT meters can give quick measurements, they are not fully reliable. The readings can be affected by inclusions or defects within the pipe/vessel wall, which can give a false low thickness reading and also by tightly adherent scales, which can give a false high thickness reading. Wherever possible full screen UT meters should be used to ensure that such features do not affect the reading, since the ultrasonic echo is displayed allowing an experienced operator to distinguish the interface formed at inclusions (false – low) and adherent scale (false – high).

When using manual meters, the reading will normally be collected from around a section of pipe (typically 100–300 mm long) or a marked out section of vessel, typically 100×100 mm to 300×300 mm in size, recording the minimum wall thickness observed within the area. For larger diameters of pipe the section may be split into four subsections (typically top, right side, bottom, and left side for horizontal pipe).

By repeating wall thickness measurements at intervals, an estimate of the corrosion rate can be obtained. In all cases, UT equipment should always be operated in accordance with manufacturer’s instructions, including calibration for the specific metal/alloy and operating temperature of the facility.

Wall thickness measurements, should be trended over a period to identify changes in condition and rate of metal loss. A typical example is shown in **Figure 11**; here data are initially collected at nominally three yearly intervals (period 1) and shows an estimated corrosion rate of 0.05 mm year<sup>−1</sup>. At the

time of the next inspection a significant change is noticed with an increase in corrosion rate to  $0.3 \text{ mm year}^{-1}$ , as a consequence the inspection frequency was changed to annually and this rate is seen to continue for a few years, until corrosion control is reestablished (period 3) with corrosion rate back to  $0.05 \text{ mm year}^{-1}$ .

This also shows the advantage of obtaining both 'short' and 'long' corrosion rates from inspection data. 'Short' corrosion rates are taken at the penultimate and ultimate (i.e. most recent) readings, while 'long' corrosion rate is based on the first reading and last reading; in the example in Figure 11 this is  $0.1 \text{ mm year}^{-1}$ .

When using UT inspection as part of corrosion monitoring activity particular attention should always be given to identification and measurement of localized corrosion (pitting), especially in sour systems.

Increasing use is being made of long-line UT, where a series of sensors are fixed around a pipe sending signals along the pipe transversely identifying possible defects up to 20–50 m in either direction from the sensors. The distance that the long range UT can effectively scan is a function of pipe geometry, number of fixings/supports (that provide 'false' echoes) and whether the pipe is buried or not. When buried the acoustic impedance is lost such that the signal 'leaks' into the ground, limiting the effective distance. Once possible defects are located then they should be confirmed using standard UT inspection.

Other methods for providing a rapid inspection of pipework are also used and continue to be developed.

These include magnetic and hall-effect (eddy current) systems and pulse eddy current, that is used to detect metal loss under insulation.

For pipelines the most common inspection method is inline inspection (ILI), also referred to as intelligent pigging or smart pig (notwithstanding the problem of nonpiggingable pipelines as highlighted earlier). Today ILI is a routine method of assessing FFP of pipelines and it can be applied to a wide range of sizes (6" up to 36" diameter) and can be deployed in any type of pipeline (i.e., oil, gas, water) and for long distances. The actual distance that can be surveyed in one deployment is dependent on the memory capacity of the tool but typically up to 100 km per deployment can be accommodated.

There are two different types of ILI tool deployed, the most common type utilizes MFL that measures wall thickness by the distortion of the magnetic signal generated by the tool caused variations in thickness of the pipeline wall. The second type is an ultrasonic tool that measures wall thickness in the same way as normal UT inspection. MFI tools can be used in any media, liquid or gas, but UT tools can only be used in a liquid media to allow acoustic coupling between the sensors and the pipe wall, and hence are not normally used gas lines.

Both MFI and UT tools detect and quantify metal loss and can identify whether the loss is internal or external. The requirements for ILI surveys are governed by International Standards, including NACE RP0102,<sup>73</sup> NACE TR 35100<sup>74</sup> and API STD 1163.<sup>75</sup>

Figure 11 Example of UT Inspection data with time (indicative).

#### 4.41.6.3 External Protection

Performance assessment of the external corrosion control system, typically coatings and/or CP will also be required. For operating plants, this will normally be limited to visual inspection, but for items that are insulated a more detailed inspection plan will be required, which will be based on risk assessment for CUI and may also include specialist NDT/NDE systems such as pulse eddy current, long range UT, radiography or thermal imaging systems.<sup>58,59</sup>

For buried and submerged pipelines, in addition to use of ILI surveys, the condition of the protective coating and effectiveness of the CP system will also be determined by one or more specialist pipeline surveys. For subsea pipelines inspection will normally be by a remote operated vehicle (ROV) carrying out both visual inspection but also potential measurements to determine the performance of the CP system.

For onshore (buried) pipelines a number of different surveys are carried out,<sup>76</sup> covering:

- close interval potential surveys (CIPS);
- pearson surveys;
- DC voltage gradient (DCVG);
- AC voltage gradient (ACVG).

Often a pipeline survey will combine two of the methods, in particular CIPS and DCVG, the aim being to identify areas where either the protection potential is less than required (typically a polarized or 'instant-off' potential more negative than  $-850$  mV versus Cu/CuSO<sub>4</sub> reference electrode), and/or where there is evidence of significant coating damage.

Pipeline survey data, together with information from fixed monitoring points, will be used to assess overall performance of the pipeline protection and to identify areas where excavations of the pipeline may be required for direct assessment of the condition. In particular for buried pipelines a growing concern relating to buried pipelines is the risk of EAC, typically associated with specific local ground conditions/chemistry, damage to protective coatings and poor/inadequate CP. EAC is described in other chapters in this book and direct assessment issues are described in more detail in [Section 4.41.6.8](#).

The management of external corrosion and maintenance of coatings on structures, piping, handrails, walkways, and gratings has been addressed using a risk based assessment (RBA) to prioritize work based on inspection of coatings condition linked to performance monitoring on a visible KPI reporting system<sup>3,77</sup> (see also [Section 4.41.6.10.4](#)).

#### 4.41.6.4 Chemical Treatment

Chemical treatment of process and service fluids is widely used in oil and gas production and processing in order to manage corrosion. Commonly used chemical treatments are:

- corrosion inhibitors;
- methanol;
- H<sub>2</sub>S scavenger;
- glycol;
- wax inhibitor;
- biocide;
- O<sub>2</sub> scavenger;
- sodium hypochlorite;
- scale inhibitor;
- pH buffer;
- antifoulant.

The purpose of each of these treatments may not necessarily be for corrosion management, but they do contribute toward corrosion mitigation and control.

Chemical selection should include performance and compatibility testing and feasibility studies prior to implementation. Part of the ongoing corrosion management process is ensuring that the correct chemical is fed at the correct dose rate/concentration at the correct location at the correct time and that there is always stock available. This is the key to the production process running efficiently and effectively.

The background to some of the different analysis issues is summarized in the following section.

##### 4.41.6.4.1 Temperature, pressure, CO<sub>2</sub>/H<sub>2</sub>S content

Temperature and pressure measurements will be routinely recorded by the plant DCS. These values, together with CO<sub>2</sub>/H<sub>2</sub>S content, can then be used to provide an estimate of the system corrosivity using any of the standard corrosion modeling software packages, for example, De Waard and Milliams,<sup>25</sup> ECE4,<sup>27</sup> Norsok M506,<sup>26</sup> etc.

There are methods for measuring dissolved CO<sub>2</sub>/H<sub>2</sub>S in water samples taken from the process. However, dissolved CO<sub>2</sub>/H<sub>2</sub>S content is highly dependent on pressure and temperature (since gas flashes off from solution when samples are depressurized and H<sub>2</sub>S is rapidly lost by air oxidation) and therefore results can be erroneous. Measured values in water are always lower than true values in the case of pressurized samples, unless elaborate sampling procedures are followed.

Hence, in the authors opinion, the preferred method would normally be to measure CO<sub>2</sub> and H<sub>2</sub>S content in associated gas (ppmv values) using sampling tubes, and then use a PVT model (e.g., Multiflash™) in conjunction with known pressure and temperature data to back calculate the dissolved CO<sub>2</sub>/H<sub>2</sub>S content of the aqueous and oil phase(s) *in situ*, throughout the system. In addition to providing a more accurate assessment it also means that only one measurement per fluid stream is required as opposed to multi-measurements at different points in the stream.

#### 4.41.6.4.2 pH measurements

The corrosivity of a solution is directly related to the solution pH, hence a measure of pH can be used to monitor changes in system corrosivity. In oil field systems pH measurement is normally carried out on fluid samples, with measurement either in the field shortly after taking the sample, or later in the laboratory. On-line pH measurements, while possible, are unreliable in oil field systems due to contamination of pH electrodes by oil and/or H<sub>2</sub>S.

The biggest problem with on-site measurements is the massive and rapid rise in pH almost immediately on depressurization of a sample, due to flashing-off of gas. *In situ* pH is almost always dominated by the CO<sub>2</sub>/bicarbonate buffer system, so the concentration of dissolved CO<sub>2</sub> greatly influences the pH and it changes greatly from downhole to wellhead to separators to export system. Laboratory measurements of pH on degassed or partly degassed samples are of no value.

Hence, the optimum procedure is to calculate pH throughout all stages of fluid handling from pressure and temperature data, gas phase CO<sub>2</sub> and water composition (salinity and mineral bicarbonate content), using standard software packages, such as NORSOK M506<sup>26</sup> or others.

#### 4.41.6.4.3 Oxygen monitoring

For seawater injection systems the principle method of corrosion control is deoxygenation, typically to < 10 ppb. Hence, a measure of oxygen content provides a direct measure of the effectiveness of the corrosion control system. Oxygen measurement can be carried out on-line or on liquid samples.

On-line measurements can use either specialist oxygen monitors or galvanic probes.<sup>78</sup> Oxygen monitors give a direct measure of the oxygen content and, provided that they are correctly serviced/calibrated (to prevent fouling of the electrode).

Galvanic probes (with elements of carbon steel and copper) can be more robust for some field applications. Although they do not give a direct measure of the oxygen content, the measured galvanic current is directly proportional to the oxygen concentration in the process stream.

#### 4.41.6.4.4 Iron count

A common and relatively straightforward method for assessing corrosion in water (e.g., seawater injection, process water, etc.) is *iron counts*; that is the measure of soluble iron ion (Fe<sup>2+</sup>).<sup>66</sup> If the corrosion is occurring the Fe<sup>2+</sup> concentration will increase. Hence, ideally, iron content at the both start and end of the system/pipeline is needed to provide an estimate of the corrosion occurring; however, in most cases simple changes in Fe<sup>2+</sup> content are used to assess increasing/decreasing corrosion conditions.

However, iron counts are only viable where the corrosion product is soluble. Hence, they are not suitable for use in sour environments (where the corrosion product is insoluble iron sulfide, FeS) or in sweet systems with a high bicarbonate content (once the process becomes FeCO<sub>3</sub> saturated, any increase in corrosion rate cannot add extra iron to solution, instead more insoluble iron carbonate scale forms). In both cases misleading information will be obtained.

#### 4.41.6.4.5 Inhibitor residuals

Inhibitor residuals are an important measurement to check that sufficient corrosion inhibitor is injected into the system. In most cases, the method of testing will be provided by the chemical vendor and will be targeted for the specific active component of the inhibitor package. However, experience has shown that some methods used are subject to interference and hence can be unreliable. Generic methods are available that can provide a reliable result, provided that they are calibrated for the specific chemical. Further details on corrosion inhibitors is given elsewhere in this book and in EFC publication.<sup>30</sup>

#### 4.41.6.5 Data Management

Is it essential that data collected as part of the corrosion management process are stored in an efficient manner that enables easy retrieval and trending of data.

A large number of commercially available systems are available that offer a varying level of interaction with process monitoring systems (e.g., PI® and SCADA®) and planning systems (e.g., Maximo® and SAP®) as well as various GIS systems and web

interfaces to enable user remote access. The level of support from the suppliers of commercially available systems can vary from a simple software sale to a fully supported service agreement. In addition a bespoke system can be developed that increase the level of flexibility required.

Stand alone systems can easily be developed for activities such as Corrosion Risk Assessment (CRA), RBA, Inspection Planning, storing Inspection Data, storing Corrosion Monitoring/CP Data, storing fluid data, and monitoring KPI's. There can be advantages when using a simple system compared with a large multifunctional database and the merits of each should be assessed.

When selecting a data management system for a facility consideration should be given to

- Type of asset:
  - Pipeline networks have a limited number of 'data locations' but a large number of data measurements and therefore require a system that can enable easy trending of data (e.g., CP data, Corrosion probe data).
  - Process plant typically has a large number of 'data locations' and a limited number of data measurements (e.g., NDT inspection data).
  - Consideration must be given to how manually generated data (e.g., Corrosion Coupon analysis and fluids analysis) are to be integrated into the data management system.
  - Is the database expected to be a complete asset register, or just consider key high-risk areas?
- Expected degradation mechanism/type of data to be collected:
  - For time-dependent degradation trending of inspection and monitoring data is appropriate.
  - For cracking mechanisms, trending of inspection data has a limited value and recording of fluid and operating parameters are of more significance.
  - Is trending of fluid monitoring data essential? What parameters are key?
  - Is the system to be used to monitor, trend and report KPIs
- National legislation:
  - If the national legislation defines a prescriptive inspection approach there is little point in trying to implement a data management system that calculates RBI frequencies.
- Level of IT infrastructure in place:
  - Where IT infrastructure is limited there is little point in trying to implement a fully automated

system. A fit for purpose procedure driven system is sometime far more appropriate.

- Roles and responsibilities:
  - Clearly defined roles and responsibilities are required for data collection, data input and data review/analysis.
  - All data systems should have a level of security that enables competency levels to be assessed better access to the system.

While data management systems are an essential tool as part of a Corrosion Management system, user intervention, audits and continuous improvement process are essential to maintain a database that is truly representative of the facility in terms of physical and operational information and perceived degradation threats. Any database that is not maintained as a live system cannot be considered an effective Corrosion Management tool.

#### 4.41.6.6 Change in Process Conditions

The original corrosion risk assessment carried out at the FEED and/or design stage will have taken a range of operating conditions from the basis of design for the particular field/facility. This in turn will have driven the material selection, corrosion control, and planning inspection/monitoring for the system once in operation. However, as highlighted at the start of this section, there is always the chance that the actual operating conditions will be different to those envisaged. This is often due to change in conditions as the facility ages/expands.

Many operators handle possible changes in process conditions by predefining the corrosion 'window' or 'envelope' (that is the range of conditions to which the original assumptions remain valid) as part of the original risk assessment carried out during FEED or Design stage. Then if any of the parameters change sufficiently with time such that they are no longer in the 'corrosion window' then they will automatically trigger a reassessment of the corrosion risk. In fact most ongoing corrosion risk assessments simply start with checking whether the operating conditions are within the original design assumptions ('window') and if they are and the performance has also been demonstrated to be in line with predictions then this is taken as sufficient to keep the existing corrosion risk assessment in place.

If the conditions have changed then the likely effect, for example, increase water cut, gas lift resulting in increase in CO<sub>2</sub> content, reduction in flow rates, etc., on the expected corrosion rate, location

and morphology should be determined and, where necessary, a change in the inspection/monitoring/corrosion control plans put in place.

#### 4.41.6.7 Risk Based Inspection (RBI)

RBI schemes are a key component of corrosion management schemes and provide a planning tool to develop the optimum plan for the execution of inspection activities. RBI uses the findings from formal risk analyses, including corrosion risk assessments, to guide the direction and emphasis of the inspection planning and the physical inspection procedures.

A risk-based approach to inspection planning is used to:

- ensure risk is reduced to as low as reasonably practicable;
- optimize the inspection schedule;
- focus inspection effort onto the most critical areas;
- identify and use the most appropriate methods of inspection.

RBI methodologies are well described in published documents such as API 581<sup>10</sup> and DnV RP G-101<sup>11</sup> and have been adopted by many operators, further details on this topic are also given in the chapter on **Risk Based Inspection** in this book.

Where RBI schemes are used, it should be noted that the determination of future inspection requirements, by extrapolation of historical trends, is based on an assumption that the conditions in the future are similar to those in the past and that there is no change in degradation mechanism(s). Any significant change in operating conditions (for example, water break-through, increase in CO<sub>2</sub> content, change in wax or scaling tendency, etc.), could result in significant changes in corrosion rate and/or corrosion damage, which could in turn lead to different inspection requirements. It is therefore appropriate for the model that is driving the RBI scheme to be rerun either at specific time intervals, or when a process variable exceeds a previously agreed boundary condition.

On new assets or in the absence of good quality historic data on mature assets, it is normally considered good practice to carry out a baseline survey to establish a known condition from which to monitor.

Many RBI schemes are operated as part of a major inspection software database and analysis tool and are normally applied to process plant and facilities. However, many standard RBI software systems can be very 'data hungry,' that is unless the majority (if not all) of

critical information is available standard software systems will not run. To overcome this limitation, 'high level' assessment schemes are being developed that allow engineering judgment to be used to where data is sparse.<sup>79</sup> High-level risk assessment for pipeline operations have also been developed.<sup>28,45,80</sup>

#### 4.41.6.8 Direct Assessment Procedures

For onshore pipelines, a major change in operational corrosion management has occurred over recent years, where the methods of '*direct assessment*' are now routinely used, and in some countries have become mandated. Here *direct assessment methodology*, actually covers a wide ranging assessment of the likely pipeline condition as determined by a review of the design, installation, geographic, operational and ILI data to identify the sections of the line that are most at risk of corrosion degradation, both internal and external, that should be selected for excavation and physical confirmation of condition (i.e., *direct assessment*).

At this time, direct assessment procedures have been developed and adopted as a number of NACE Standard Practices for:

- Pipeline External Corrosion Direct Assessment Methodology (EC-ECDA); NACE SP0502–2008.
- Stress Corrosion Cracking (SCC) Direct Assessment Methodology (SCC-ECDA); NACE SP0204–2008.
- Internal Corrosion Direct Assessment Methodology for Pipelines Carrying Normally Dry Natural Gas (DG-ICDA); NACE SP0206–2006.
- Internal Corrosion Direct Assessment Methodology for Liquid Petroleum Pipelines (LP-ICDA); NACE SP0208–2008.

A further NACE standard, for internal corrosion due to wet gas operation (WG-ICDA) is currently under-development and is expected to be published by 2010.

In all cases the direct assessment methodology requires a detailed analysis of existing data to determine whether or not there is sufficient information so that the methodology can be applied and provides guidance for what critical information needs to be obtained.

Once sufficient data have been collected, the methodology provides a structured procedure to analyze the data to highlight areas of specific corrosion risk. This normally requires dividing the pipeline into different sections (lengths) where the conditions are likely to be similar.

- For internal corrosion assessment, sections will be defined by significant changes in operating pressure/temperature/flow rates, and especially angle of inclination, since this will define where water drop out and collection will occur and hence the most likely place for corrosion to occur;
- For external corrosion assessment, sections will be defined by changes in ground (soil) condition, CP systems, etc.

The comparison of the analysis of theoretical conditions together with pipeline inspection data, such as ILI surveys (to identify both internal and external features) and external surveys (CIPS, DCVG – to identify areas of coating damage and/or under protection), is used to prioritize areas to be excavated and examined, usually by UT inspection.

The whole process provides a transparent method of assessment and ensures that high-risk areas are correctly identified and actions taken in a timely manner, and is essentially a pipeline equivalent to process facility RBI schemes.

#### 4.41.6.9 Fitness for Service (FFS)

As highlighted previously, the main objective of corrosion management is to ensure that plant and facilities are operated in a safe and reliable manner and the principle challenge for corrosion management in the oil and gas industry is that the preferred material of construction (low-alloy carbon steel) can, and is, subject to both internal and external corrosion, especially where the corrosion control plans do not operate as intended.

Hence, an important aspect of corrosion management is assessing the condition and FFS for items of equipment (pipeline, pipework, vessels, tanks, etc.) where corrosion has been found. FFS assessment (also referred to as FFP) can be simple to the complex, depending on the component, the extent and type of deterioration, and regular requirements. API 579<sup>81</sup> defines three levels of assessment, as:

- **Level 1** FFS assessments provide conservative screening criteria that require the least amount of inspection and component information. Level 1 assessments usually do not require extensive calculations. Either inspectors or plant engineers will conduct a Level 1 assessment.
- **Level 2** FFS assessments involve a more detailed evaluation of components and usually require an accurate measurement of flaws or damage. Most Level 2 FFS assessments require calculation of the required component thickness or of component stress. Either plant engineers or engineering specialists will conduct Level 2 assessments.
- **Level 3** FFS assessments require detailed evaluation of components. Component flaws or damage must be accurately determined, and calculation methods often involve numerical analysis such as the finite element method. Level 3 assessments often require the services of engineering specialists experienced in advanced stress analysis, fracture mechanics, etc.

A Level 1 assessment could be as simple as confirming whether any metal loss is within the design corrosion allowance (i.e., based on the original design pressure). If metal loss exceeds this limit, then the item may still be suitable for service, but only at a reduced maximum operating pressure (as described in API 570<sup>57</sup> and ASME B31G<sup>82</sup>), this would form part of a Level 2 assessment.

Level 3 assessments apply to more complex conditions, in particular localized corrosion and/or EAC, where alternative methods of assessment may be required. The specific method/procedure to be used will be dependent on component type, original design code and nature of damage, for example, API 579,<sup>81</sup> ASME B31G,<sup>82</sup> DnV RP F-101,<sup>83</sup> BS 7910,<sup>84</sup> and others.

#### 4.41.6.10 Communication and Management Structure

##### 4.41.6.10.1 Corrosion management team

The corrosion management team is the main vehicle for communication between the key players. Communication within the operator's organization and its relevant contractors is also important in order to achieve understanding and obtain support in meeting objectives:

- Appropriate information should be disseminated to the correct people.
- Written information on hazards, risks and preventative measures should be provided.
- Procedures, work instructions, and guidelines should be published and shared.
- Corrosion awareness information should be distributed to those who need to be aware of the importance of corrosion management to assist those directly involved. Training and information to develop corrosion awareness should be provided.
- Key players in the organization and their contracted bodies that comprise the corrosion management team should be identified.

- Regular meetings of the corrosion management team on implementation status, trends in deterioration and failure, status of corrective action, and planning and budgetary issues should be undertaken.
- Managers, technical specialists, authorities, supervisors, and wherever appropriate, contractor personnel should be visible through the publication of charts and guides.
- Experiences should be shared with other facilities, other operators and with appropriate external bodies.

#### **4.41.6.10.2 Management of change**

Management of change is an important part of corrosion management activity. As described previously, it is vital that changes in operating conditions are identified and their impact on the corrosion risk and effectiveness of the corrosion control program including the inspection/monitoring plans are assessed.

Most oil and gas operating companies will have a management of change procedure, so that as new developments are planned and existing facilities are phased out the engineering impact is fully considered and implications for fabrication, maintenance and operations are put in place. The corrosion management team should be included within the management of change process ensuring that implications to operational windows, and effects on corrosion risk are identified early in the change process so, as was the case during initial design, cost-effective procedures can be developed in a timely manner.

In the case of new development/tie-ins, etc., a policy should be adopted regarding the required life of the facility. The materials and corrosion control aims at providing that life. To maintain design intent and operate within the design limits, the plan should identify the elements to be built into the design, the performance limits on which it is based and the actions required during operation. If there is a choice of suitable materials then life cycle costing can be used to identify the final materials. The development plan should consider that the design should make provision for monitoring equipment such as corrosion probes, access fittings, instruments and the provision for data gathering. Also, design to enable inspection such as pig traps suitable for online inspection tools should be considered.

In the case of field extension, as technology advances, asset life expectancy is increasingly being extended beyond the original design life. Therefore, it is important to be able to accurately gauge the control

status of the asset if field life extension is required. This might require a reappraisal of corrosion risks and introduction of major changes to current activities. The individuals responsible for setting and implementing the corrosion management strategy and strategic plan should be made aware of the future business and operational requirements of the asset.

#### **4.41.6.10.3 Contracting structure**

There are many different operational and contractual structures adopted by operators world-wide. These range from all staff (management, engineering, operating, inspection and maintenance) being employed directly by the operator to fully out-sourced conditions, where with the exception of management and senior engineering functions, all other roles are let on a contract basis to either a main operation/maintenance contractor or as a series of contracts for specific roles.

In all cases, the roles and responsibilities for the different disciplines/contractors/subcontractors relating to corrosion management should be clearly identified. Reporting routes should also ensure that relevant information/data passed sideways to other corrosion management team members allow timely review and action. There are many cases where information relating to problems with, for example, corrosion inhibitors, high measured corrosion rates, changes in operating conditions, etc. are not identified or not passed to the responsible person/department until it is too late to provide cost-effective intervention.

#### **4.41.6.10.4 Key point indicators (KPI)**

KPIs are used as a measure of the integrity of the facility and the corrosion management system. KPIs should be:

- Relevant, practicable, and meaningful to the corrosion threats and the policy and plan in place.
- Quantifiable to avoid subjective judgments.
- Intended primarily at demonstrating success or identifying trends that enable corrective action.
- Determined with reference to the engineering design of the facility in terms of performance limits for corrosion barriers. Target values should be set for all indicators.
- Selected so that they indicate how successfully the plan is being implemented linked to corrosion – proactive measurement and leading indicators.
- Selected so that they indicate trends toward the achievement the desired outcomes linked to

corrosion – reactive measurement and lagging indicators.

KPIs allow quick indication of where corrosion management schemes are working and, more importantly, where they are failing, either due to failure to meet specific objective (e.g., delays in the retrieval of corrosion coupons, delays to planned inspection, insufficient dosing of chemicals, etc.) or where corrosion control is compromised (e.g., increased in measured corrosion rate above critical limits). There are various ways of presenting KPI information, increasing so-called ‘*traffic light*’ systems (with KPIs reported as ‘red,’ ‘amber,’ or ‘green’) are used,<sup>3</sup> for example, as shown in [Table 1](#).

In addition to using KPIs for assessing the performance of the management system as a whole, technical KPIs can also be used to highlight the performance of the corrosion control plans. Here, similar arrangements would apply but criteria based on acceptable/expected corrosion rates, bacteria counts, inhibitor residual concentrations, etc. would be used.

#### 4.41.6.10.5 Audit/compliance

An important aspect of modern corrosion management systems is that they should provide a clear and transparent approach to the decision-making process, the overall performance of the corrosion monitoring plan, and the performances of the corrosion control procedures adopted.

Part of this process is that the system should be subjected to regular audits (internal and external) to

determine whether the corrosion management system effectively conforms to the requirements. They are an essential check on the performance of the system and are normally carried out by an independent party (i.e., somebody not directly involved in the operation of the corrosion system). Audits cover the following aspects:

- implementation of procedures and processes;
- competency;
- checks in place;
- compliance.

An audit reviews the processes and procedures that are aimed at achieving the performance targets and determines if the procedures for ensuring that they are achieved are being properly implemented. If activities are found to be not in accordance with the procedures and processes it is called a noncompliance.

Audits can be performed in two ways. A complete audit can be undertaken in one exercise or individual elements can be audited separately on a rolling basis. An audit cycle duration is generally 2 to 3 years. In addition to independent audits, internal audits should be carried out more frequently in specific procedures or functions.

The procedures of contractors will be audited on award of contract if not covered by prequalification and then periodically in the same manner as for the operator.

#### 4.41.6.10.6 Ongoing improvements

As identified in the corrosion management overview chapter in this book, an important aspect of any

**Table 1** Examples of corrosion management key performance indicators for an offshore facility (partial extract from Guidance for Corrosion Management in Oil and Gas Production and Processing<sup>3</sup>)

Activity	Target	Green	Amber	Red
<b>Plan</b>				
RBI reviews up to date	None outstanding	None	2 or less	3 or more
Annual pipework inspection scope	Completed by year end	Yes		No
Annual vessel inspection scope	By end of Jan	Jan	Feb	Mar or later
<b>Implement</b>				
% pipework inspections on target	>90% of planned cumulative completion	>90% complete	75–90% complete	< 75%
Safety critical vessel inspections on target as per RBI due date	On target or above	All on target (0)	2 below target (1–2)	>2 below target (≥3)
<b>Measure</b>				
No of leaks (safety or production critical)	No leaks	0		≥1
No of unexpected leaks (noncritical)	No leaks	0	≤4	≥5
<b>Review</b>				
Bi-monthly pipework integrity summary been updated	100% complete	Yes		No
Annual report completed (1Q)	Complete report within Q1	Yes		No

system is its ability to develop and improve with experience. Hence, the system should regularly review its performance and determine where it is meeting and nonmeeting its targets. This is often referred to as 'do and improve loops.'

#### 4.41.7 Summary/Conclusions

The management of corrosion in oil and gas production has a long history of pioneering developments and has been instrumental in progressing many successful field applications that would have been unthinkable 25 years ago. In particular, the 'FFS' of materials for sour service is increasingly allowing more aggressive conditions to be handled, while improvements in corrosion inhibitors has enabled multiphase lines to have increased throughput even under erosive conditions. Hand in hand with these technical developments has been an increased awareness of the need to manage SHE issues, hence corrosion mitigation activities are increasingly seen as having an important impact on integrity and loss containment.

The aim of the chapter was to identify some of the basic corrosion inputs into projects during the main development phases. Much of the detail can be found in industry and international standards quoted throughout the text (NACE, API, DnV, ISO) and industry relevant publications such as the *Corrosion Threats Handbook – Upstream Oil and Gas Production*<sup>5</sup> and *Guidance for Corrosion Management in Oil and Gas Production and Processing*.<sup>3</sup> These publications provide good examples of the corrosion damage sustained by process equipment during operational life and the detailed requirements and performance indicators needed to ensure that corrosion is managed effectively to maintain asset integrity.

The increasing demand for improvements in all aspects of asset management will impact on the delivery of corrosion services as more aggressive environments are exploited. Although driven primarily by SHE concerns, a continuous improvement in management systems, involving the use of performance indicators, reviews and audits of activities should also result in improvements in operational and day to day activities to deliver less unscheduled downtime and improved performance. The importance of a good record keeping/data management system cannot be over emphasized as field data are vital to provide the information needed for good decision making.

## Glossary

**Drip** A drip is a leg located underneath the pipeline that collects liquids and solids that can be transported down the pipeline with the product. Drips are usually equipped with a siphoning arrangement so that the collected materials can be removed.

**Electric resistance welding** Electric resistance welding is a process used to weld the longitudinal seam. The heat required for welding is produced by the resistance of the steel to the passage of an electric current. The heated plate edges are then forced together under pressure to produce the weld.

**Groundbed** A groundbed is one or more anodes installed in the earth to provide a low-resistance electrical path to ground in cathodic protection systems.

**Lack of fusion** A lack of fusion defect is a region of the weld where full fusion has not been

achieved. This could be due, for example, to mill scale on the plate edges or a lack of adequate heat or pressure during the welding process.

**Linepipe** An individual length of pipe (sometimes also referred to as a spool or joint), typically 12m in length.

**Town gas** Town gas is a type of manufactured gas that is principally made from coal. Town gas was used extensively in homes in the UK until the discovery of natural gas.

## Abbreviations

**In-line Inspection (ILI)** Pipeline inspection conducted using an instrumented vehicle that travels inside the pipeline usually propelled by the fluid in the pipe.

### Symbols

- $V_{IR}$  Potential drop associated with the flow of Cathodic Protection current through the soil of finite resistance (mV)
- $V_p$  Actual potential on the pipe surface (mV)
- $V_s$  Cathodic protection potential measured on the surface (mV)

## 4.42.1 Introduction to Pipelines and Pipeline Engineering

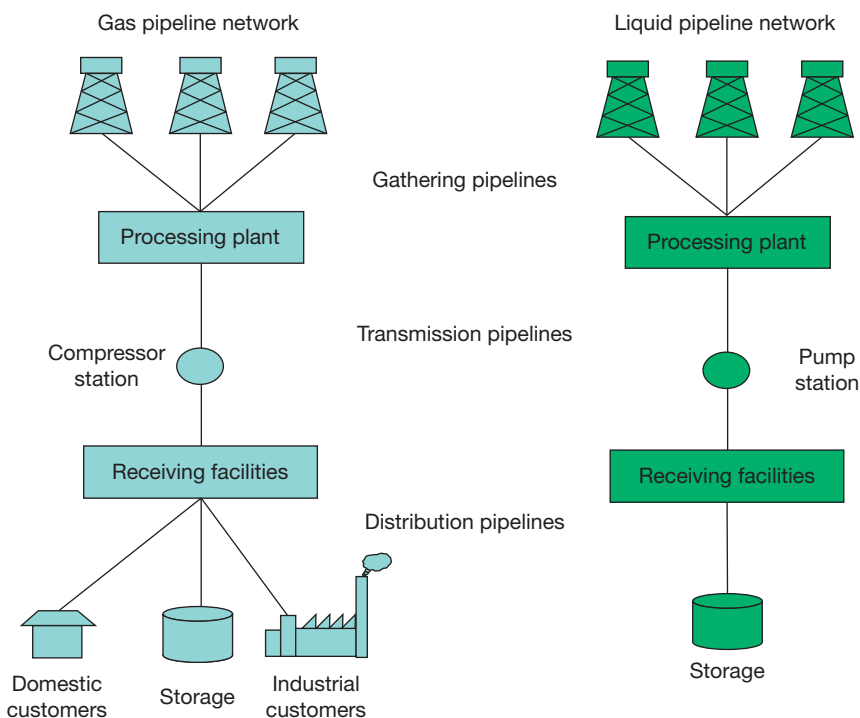

The first recorded use of pipelines for the transportation of natural gas was ~400 BC when the Chinese used bamboo pipe to transport natural gas to Peking to be used for lighting. Since then pipelines have become the principle method for the transportation of natural gas and hazardous liquids, and currently, it is estimated that there are over 3.5 million kilometers of pipelines installed worldwide.<sup>1</sup>

Pipelines can be categorized according to their location (onshore or offshore), the product carried (liquids, gases or multiphase, that is, mixtures of gases and liquids), or the purpose of the pipeline.

To explain this last category, consider the schematic of [Figure 1](#), which shows a typical pipeline network for oil or gas transportation. This network starts with the gathering system, which transports the product from the wells to a processing station or a transmission line. The transmission pipeline network links the gathering system to the distribution system. Finally, the distribution system transports the product from a distribution point to the point of end use or storage and typically consists of low-pressure gas pipelines for domestic and industrial use.

The relative size of each of these pipeline systems is illustrated in [Table 1](#) for the US pipeline network.<sup>2</sup> These figures show that the distribution system is by far the largest part of the network. However, the focus of this chapter is to investigate the effects of corrosion on the high-pressure onshore gathering and transmission pipelines that transport natural gas and hazardous liquids. Over 98% of the world's pipelines are buried and therefore emphasis is placed on the management of both internal and external corrosion and stress corrosion cracking (SCC) in these types of pipelines.

Having defined the scope, it is important to first investigate the scale of the corrosion problem, both in terms of the cost of corrosion and the impact of corrosion on pipeline safety.

**Figure 1** Schematic representation of a typical pipeline network.

**Table 1** Distribution of US pipelines by usage (Statistics for 2006)<sup>2</sup>

<i>Pipeline category</i>	<i>Total length (miles)</i>	<i>Total length (km)</i>
Onshore gas gathering	13 056	21 012
Offshore gas gathering	7331	11 798
Onshore gas transmission	293 622	472 539
Offshore gas transmission	6699	10 781
Distribution	1 182 534	1 903 102
Liquid transmission	166 481	267 925

#### 4.42.2 Introduction: The Scale of the Corrosion Problem

In 2002, the Federal Highway Administration (FHWA) in the US published the results of a two-year study to determine the cost of corrosion to the US economy.<sup>3</sup> One of the 26 sectors investigated in the study was gas and liquid transmission pipelines. (It should be noted that in this report the term transmission pipelines included the gathering system.) In this sector, the cost of corrosion was estimated at between \$5.4 and \$8.6 billion every year.<sup>4</sup> This cost was reported in three areas: the cost of failures (10%); the capital costs related to installing a corrosion control system and the replacement or repair of pipelines (38%); and operations and maintenance costs related to controlling corrosion on the pipeline and ensuring that the control systems remain effective (52%). Included in the cost of failure is the loss of throughput, and therefore revenue, and also estimates for fatality and injury compensation and legal costs for liability.

Corrosion is therefore a significant cost to the pipeline operator in the operation and maintenance of a transmission pipeline; however, it is important to understand the threat of corrosion in relation to other threats on the pipeline. One of the most rigorous means of achieving this perspective is through the analysis of pipeline failure statistics.

##### 4.42.2.1 Pipeline Failure Statistics

A number of organizations worldwide collect statistics on the frequency and causes of pipeline failures. In the United States, the Office of Pipeline Safety (OPS) within the Department of Transportation (DOT) regulates the safety aspects of pipelines. Natural gas and hazardous liquid transmission,

distribution, and gathering companies are required by law to report to the DOT all serious and significant incidents involving a release from their pipelines, which involves either:

- a death or injury requiring in-patient hospitalization;
- total costs of \$50 000 or more measured in 1984 dollars (including, for example, lost product and repair costs);
- highly volatile liquid releases of five barrels or more or other liquid releases of fifty barrels or more; or
- liquid releases resulting in an unintentional fire or explosion.

The statistics are available from the DOT website from 1986.<sup>5</sup> However, the reporting categories for transmission pipelines changed in 2002, and therefore, it is difficult to compare statistics for some failure types.

CONCAWE, a group of European oil companies committed to environmental research, has systematically collected information on oil spills since 1971 and has reported the outcome annually ever since. In 2004, the database included over 35 000 km of onshore oil pipelines.<sup>6</sup> The CONCAWE statistics record any spill of greater than 1 m<sup>3</sup>, which is more rigorous than the requirement in the US and therefore care has to be taken when comparing data from these sources. Equivalent data for the European gas transmission system are collected by EGIG (European Gas Pipeline Incident Data Group). EGIG has collected data since 1970 on unintentional releases of gas from onshore steel pipelines with a design pressure greater than 15 bar. Over 122 000 km of the European gas pipeline network was included in the 2004 EGIG incident report.<sup>7</sup>

In the UK, the UK Onshore Pipeline Association (UKOPA) has also compiled a database of product loss incidents for nearly 22 000 km of Major Accident Hazard Pipelines (MAHP) as specified by the UK Pipeline Safety Regulations,<sup>8</sup> which includes natural gas, ethylene, and crude oil.<sup>9</sup> The database records all unintentional releases from pipelines in the public domain (i.e., outside the fences of installations) but does not include releases from ancillary equipment such as valves and compressors.

##### 4.42.2.2 Causes of Pipeline Failures

Using data from the failure statistics, it is possible to build up a picture of the role of corrosion in pipeline incidents, although it is highlighted that direct comparisons between data sets should be treated with

caution as the categories under which failures are reported differ between the databases.

One immediate conclusion that can be drawn from the analysis of the pipeline failure data for the years reviewed is that corrosion does not pose the most severe threat to pipeline integrity. In fact, in the OPS, CONCAWE, and EGIG databases, the majority of pipeline incidents result from external interference, that is, an outside force, such as an excavator striking the pipeline, whether intentionally or unintentionally. Corrosion accounts for the second largest number of spills in the CONCAWE (Table 2)<sup>6</sup> and OPS databases and the third largest number of incidents in the EGIG database (Table 3). The UKOPA database presents a slightly different picture in that the data are skewed by historical failures that occurred due to internal cracking when the system was transporting wet town gas. However, the data do show that external interference accounts for more failures than corrosion (Table 4).<sup>9</sup>

**Table 2** Summary of failure statistics from the CONCAWE database of incidents on oil pipelines (1971–2004)<sup>6</sup>

	<i>Number of incidents</i>		<i>Percentage gross volume spilled (m<sup>3</sup>/year)</i>
	<i>Average per year (1971–2004)</i>	<i>Percentage (1971–2004)</i>	<i>1971–2004</i>
Mechanical failure	3.0	23.8	31.4
Operational	0.9	6.8	3.6
Corrosion	3.6	28.9	18.8
Natural hazard	0.4	3.5	4.1
Third party activity	4.6	36.9	42.1

**Table 3** Summary of failure incidents by cause from the EGIG database of incidents on gas pipelines (1970–2004)<sup>7</sup>

<i>Failure cause</i>	<i>Percentage of incidents</i>
External interference	49.7
Construction defect/material failure	16.7
Corrosion	15.1
Ground movement	7.1
Hot-tap made by error	4.6
Other and unknown	6.7

The failure data also allow an investigation into the dominant failure location for different categories of pipeline, that is, whether corrosion occurs predominantly on the external or internal surface of the pipeline. Table 5 provides a summary of the statistics for corrosion failures by location for transmission pipelines (natural gas and hazardous liquids) from the OPS statistics.<sup>5</sup> It is interesting to note that for hazardous liquid pipelines, the corrosion incidents in the US are primarily attributable to external corrosion, a trend that has also been observed in the CONCAWE database.<sup>10</sup> For natural gas pipelines, the OPS data show that internal corrosion accounts for the majority of corrosion failures, which is contrary to the experience in Europe. The EGIG data indicate that external corrosion is responsible for nearly 80% of all corrosion failures

**Table 4** Summary of failure incidents by cause from the UKOPA database (1962–2004)<sup>9</sup>

<i>Failure cause</i>	<i>Number of incidents</i>	<i>Percentage of incidents</i>
Girth weld defect	33	19.2
External interference	37	21.5
Internal corrosion	2	1.2
External corrosion	31	18.0
Unknown	8	4.7
Other <sup>a</sup>	40	23.3
Pipe defect	13	7.6
Ground movement	5	2.9
Seam weld defect	3	1.7

<sup>a</sup>Includes 30 failures of internal cracking due to wet town gas.

**Table 5** Summary of failure statistics from the DOT database of incidents on natural gas and hazardous liquid pipelines (1986–2005)<sup>5</sup>

	<i>Gas transmission</i>	<i>Hazardous liquid</i>
Total number of incidents	1025	2646
Total number of corrosion incidents	254	718
Percentage of total incidents due to corrosion	24.8	27.1
Percentage of corrosion incidents due to external corrosion	41.3	68.0
Percentage of corrosion incidents due to internal corrosion	58.3	30.8
Percentage corrosion incidents not specified	0.4	2.1

on the European gas system.<sup>7</sup> Even then, these statistics may be misleading as the internal corrosion failures were caused by manufactured gas and not natural gas. The dominance of external corrosion is similarly observed in the UKOPA data, which include both gas and liquid pipelines (Table 4).<sup>9</sup>

One of the issues that both CONCAWE and EGIG wanted to investigate from their statistics was whether there was any evidence that older pipelines were more likely to fail as a result of corrosion. Although the majority of oil pipelines in Europe were built more than 25 years ago, the CONCAWE statistics show that the failure rate from corrosion (i.e., the most likely failure mode with increasing age) has not significantly increased with age for pipelines up to 45 years old (Figure 2).<sup>10</sup> The statistics from the EGIG database also lead to the conclusion that there is no evidence of an ageing effect, that is, there is no increase in the corrosion failure frequency as a pipeline gets older. In fact the data show that the failure frequencies are actually decreasing with time. These conclusions demonstrate that corrosion failure on pipelines can be successfully managed through preventative inspection and maintenance measures.

The CONCAWE and EGIG databases also record information about the percentage of product volume spilt by cause. The figures for oil pipelines are reported in Table 2. In both databases, external interference results in larger releases or volumes spilled than corrosion. Data in the EGIG database indicate that this observation can be attributed to the fact that the pipeline is more likely to rupture as a result of external interference, resulting in a large hole from which product can escape, whereas corrosion is more likely to result in a leak from a small defect or pinhole.

It can therefore be concluded that although external interference accounts for the highest number of pipeline failures and a greater volume of product lost, corrosion, predominantly external, remains one of the main threats to pipeline safety. However, the statistics indicate that the corrosion threat can be successfully managed and measures put in place to detect and prevent corrosion on pipelines as part of a pipeline integrity management plan. Specific to that integrity management plan will be a corrosion management strategy in which the pipeline operator will have to optimize the cost of corrosion from an economic, environmental, and safety point of view.

**Figure 2** Relationship between corrosion spill frequency and age in the CONCAWE database.

#### 4.42.2.3 Pipeline Safety

Although the requirement to collect failure statistics may, in some cases, be regulatory, in others it is voluntary among the pipeline operators to demonstrate the inherent safety of pipeline transmission systems and also to identify the main causes of pipeline failure in order that safety improvements can be made. Indeed, one of the conclusions that can be drawn from the incident data is that pipelines are one of the safest modes of transport for hazardous liquid and gas products over long distances. A study conducted in the US, comparing incident data for pipeline transportation of oil products relative to other modes of oil transport, confirms that pipeline transport has the best overall safety record<sup>11,12</sup> (Table 6). In particular, based on this normalized data, road transport of oil resulted in 103 times more deaths and 32 times more injuries in the US over the five-year period between 1997 and 2001 than pipeline transport and this figure is increasing when compared with the previous 5 years (1992–1997). A similar trend is inherent in the statistics from Western Europe, which has caused CONCAWE to conclude that “unlike marine and road traffic accidents, so far in Western Europe nothing of large enough scale or frequency has occurred with oil pipelines to draw them to the attention of the general public.”<sup>10</sup>

Notwithstanding, in the US in the past few years there have been a number of high-profile pipeline failures, which have refocused public attention on pipeline safety. One corrosion-related failure in particular is highlighted here, which illustrates not only the severe consequences of pipeline failure but also the requirement to understand the threats to a pipeline system and to put adequate procedures in place to address the threats before incidents occur.

In August 2000, a 30" natural gas pipeline ruptured in New Mexico. The escaping gas ignited and killed twelve members of an extended family who were camping near the rupture site. Property and

other damages totaled \$998 296. The pipeline accident report concluded that the probable cause of the failure was “a significant reduction in wall thickness due to severe internal corrosion.”<sup>13</sup> The corrosion had occurred at a low point, caused by a bend in the pipeline, where water had been allowed to accumulate.

The internal corrosion control program that was employed by the operator was to monitor the quality of gas entering the pipeline, to visually inspect the inside of the pipeline when it was exposed, to run cleaning tools through the pipeline and to maintain the pipeline drips by ensuring that they functioned properly and liquids were regularly removed. However, the company procedures for gas monitoring were not rigorous enough to be able to identify whether internal corrosion could be occurring. In addition, due to the design of the drip assembly for the pipeline that ruptured, cleaning and in-line inspection and cleaning (ILI) tools could not be run in this section. As a result, the drip upstream of the rupture location became blocked, allowing liquids to bypass the drip and continue down the pipeline. Although this section of the pipeline could not be inspected using ILI, the corrosion control program did not specify additional inspection, such as ultrasonic thickness measurements at low points or the installation of corrosion-monitoring devices to determine whether corrosion was occurring. The National Transport Safety Board concluded that the corrosion had occurred because the “corrosion control program failed to prevent, detect, or control internal corrosion within the company’s pipeline.”<sup>13</sup>

Incidents such as this have resulted in the introduction of new regulations regarding pipeline integrity management in the US.<sup>14,15</sup> Many of the approaches that have been used to draw up integrity management plans have been based on risk assessment methods to ensure that the major threats are identified, prevented, detected, and controlled. The remainder of this chapter will examine the causes of corrosion, risk-based inspection and maintenance

**Table 6** Comparison of safety data for oil transport per ton mile transported (1992–2001)<sup>11,12</sup>

	<i>Pipeline</i>	<i>Trucks</i>		<i>Barge</i>		<i>Ship</i>		<i>Rail</i>	
		1992–1997	1997–2001	1992–1997	1997–2001	1992–1997	1997–2001	1992–1997	1997–2001
Deaths	1.0	87.3	103	10.2	10	4.0	10	2.7	0
Injuries	1.0	2.3	32	0.9	14	0.7	14	2.6	11

The data is presented based on a multiplier of the pipeline rate, which is given a value of one. Therefore, a value of less than one indicates a better safety record.

strategies and integrity assessments that are used in the pipeline industry to identify, manage, and control pipeline corrosion.

### 4.42.3 Pipeline Integrity Management

The role of pipeline integrity management is to increase public safety by minimizing or eliminating pipeline failures. Integrity management planning requires an operator to identify the major threats to the integrity of the pipeline and then to plan and implement inspection, maintenance, and control strategies to ensure that these threats are appropriately managed. The basic principle of pipeline integrity management planning is outlined in [Figure 3](#).

Risk assessment procedures are now being widely used in the pipeline industry as a tool to enable operators to rigorously identify the critical pipeline threats and to determine whether particular sections of a pipeline or particular pipelines in a network are at increased risk of failure. These critical areas can then be prioritized for appropriate inspection and mitigation actions implemented to address the identified threats. Risk assessment methods also allow the operators to run risk reduction scenarios in order that effort and resources can be concentrated on those activities that have the greatest impact on reducing the risk. In many countries, risk assessment forms part of the pipeline integrity management codes and regulations.<sup>8,14–16</sup>

The risk assessment approach that is adopted by the pipeline operator can be qualitative, semiquantitative, or fully quantitative. A qualitative approach is the simplest method and will provide a coarse (high,

medium, low) assessment of the risk on the pipeline, although it tends to be very subjective. A fully quantitative method may be the most rigorous approach; however, there is often not enough pipeline data and associated information available to conduct such an assessment. Therefore, most operators adopt semiquantitative methods that use scoring models to determine a relative risk score for each of the threats on a pipeline. These methods consist of a series of algorithms for each of the threats that identify the key parameters contributing to that threat and then weight the relative importance of those parameters and their contribution to the overall risk.<sup>17</sup> The benefit of semiquantitative methods is that non-subjective data, such as pipeline inspection results, can be used in the threat analysis.

The first stage in the process illustrated in [Figure 3](#) is therefore to identify the potential threats to the pipeline and to collect the appropriate data to allow the threat to be assessed. The ASME B31.8S code supplement<sup>18</sup> provides guidance for the implementation of integrity management plans on gas pipelines and identifies 22 root causes of pipeline failure that have to be addressed as part of a risk assessment. Three of these relate to corrosion: external corrosion, internal corrosion, and SCC. In order to understand the risk assessment process as it pertains to these corrosion related threats, a review of the factors that contribute to the mechanisms and control of pipeline corrosion is required.

### 4.42.4 External Pipeline Corrosion Risks

The majority of the onshore pipeline networks are constructed from plain carbon–manganese steel that is alloyed and processed to produce the required strength, toughness, and weldability properties. One of the consequences of using plain carbon steel for onshore pipelines is that it is not inherently resistant to corrosion, either from the soil environment or from potential corrosives in the product.

#### 4.42.4.1 External Corrosion: Mechanisms

In the presence of water from the external environment, either the atmosphere or the soil, unprotected carbon steel will corrode. Corrosion defects reduce the load-carrying capability of the pipeline, and if they are allowed to continue to grow, may result in leak or rupture failures. In conducting pipeline

**Figure 3** Pipeline integrity management process.

corrosion management programs, it is therefore essential to understand the type of corrosion to which the pipeline is susceptible and the rate at which that corrosion could grow. The following sections describe the main types of external pipeline corrosion and highlight the risk factors for each type.

#### 4.42.4.1.1 Soil corrosion

As with all corrosion reactions, for external corrosion to occur on a pipeline, there must be anodic and cathodic areas on the pipe surface that are electrically connected by the pipe material and are immersed in a conducting electrolyte, the soil. For buried pipelines in a wet, oxygenated soil environment, the half-cell corrosion reactions are:

The rusting of carbon steel in the soil environment can therefore be described by the general equation:

In the simplest form of corrosion, the anodes and

cathodes are distributed evenly over the metal surface and the result is uniform wastage or general corrosion. However, at times, distinct anodic and cathodic zones are formed and this results in localized pitting corrosion. Whether a particular area of the pipe becomes anodic or cathodic can be dependent on local variations in steel chemistry or soil constituents, particularly oxygen. The nature of the soil is therefore very important in the determination of the likelihood and severity of external corrosion.

In general, soils that are good conductors will produce higher corrosion rates, that is, soils with low pH values, high soluble salt content, and high moisture content. The conductivity and therefore the corrosivity of the soil are measured by its resistivity, that is, the higher the resistivity value, the lower the corrosion rate, as there is more resistance to the flow of current. ASME B31.8S<sup>18</sup> contains guidance on estimating corrosion rates based on soil resistivity measurements and site observations. Similar correlations between corrosion rate and soil type and resistivity have also been published by Simon-Thomas *et al.*<sup>19</sup> and Peabody.<sup>20</sup> All of these correlations are compared in Figure 4.<sup>21</sup> From these data, it can be seen that corrosion rates for soil corrosion are in the

**Figure 4** Comparison of external corrosion rate prediction models. Reproduced with permission from Race, J. M.; Dawson, S. J.; Stanley, L. M.; Kariyawasam, S. J. *Pipeline Eng.* **2007**, 6(1), 13–29.

range  $0.05\text{--}0.5\text{ mm year}^{-1}$  depending on soil resistivity. At the lower end of the range, corrosion rates of  $0.05\text{ mm year}^{-1}$  would be associated with soils such as limestone, sands, or gravels, which typically have resistivity readings greater than  $10\,000\text{--}20\,000\,\Omega\text{ cm}$ . At the upper end, corrosion rates of  $0.5\text{ mm year}^{-1}$  are typical for steel in peat or swamp-like terrain and correlate to resistivity readings in the range  $100\text{--}1000\,\Omega\text{ cm}$ . It is possible that even higher corrosion rates could be observed if the backfill material contains industrial waste, particularly conductive materials such as coke. The National Association of Corrosion Engineers (NACE) has conducted long-term underground corrosion tests of unprotected steel in a variety of soils. The upper 80% confidence level of these exposure tests indicates that a rate of  $0.4\text{ mm year}^{-1}$  may be typical for soil corrosion.<sup>22</sup> It should be noted that soil conditions will change along the length of a pipeline and therefore the severity of corrosion will also change. It should also be remembered that pipelines are generally buried and therefore soil conditions at the surface may not reflect those in the vicinity of the pipeline.

Although typical rates for external corrosion of pipeline steel are in the range  $0.05\text{--}0.5\text{ mm year}^{-1}$ , there are particular types of corrosion that can occur in pipelines where much higher corrosion rates can be achieved. These types of corrosion are of particular concern from a pipeline integrity management viewpoint, as they have to be identified quickly in order that mitigative measures can be implemented. These mechanisms are discussed in the following sections.

#### **4.42.4.1.2 External microbiologically influenced corrosion (MIC)**

With reference to pipeline corrosion, MIC can be defined as corrosion that is initiated and/or accelerated by the physical presence and metabolic activities of microorganisms in the soil. Although the bacteria themselves do not directly attack the steel surface, they can initiate and maintain conditions for corrosion by interacting with the electrochemical corrosion process.

Different types of bacteria found in soil have been shown to be responsible for pipeline steel corrosion. One of the key groups of microbes in this respect is sulfate-reducing bacteria (SRB). SRB are known as obligate anaerobic bacteria, which means that they become active in the absence of oxygen and thrive in waterlogged soils such as clays. One theory regarding the role of SRB in promoting corrosion is that sulfate is reduced to sulfide during the metabolic process.

The sulfide can then react with hydrogen, produced either as a result of the cathodic corrosion reaction or by further metabolic processes, to produce hydrogen sulfide. A corrosion reaction between hydrogen sulfide and iron produces an iron sulfide corrosion deposit on the surface and further corrosion of the steel occurs through a galvanic couple established between the iron sulfide deposit and the surrounding iron. Corrosion rates of between  $0.2$  and  $0.7\text{ mm year}^{-1}$  have been measured for this mechanism on pipelines in the field, although rates above  $5\text{ mm year}^{-1}$  have been cited.<sup>23</sup>

Another important microorganism in the microbiological corrosion of steel is acid-producing bacteria (APB). This type of bacteria is classed as facultative aerobic bacteria, which means that, although they prefer aerobic conditions, such as sandy soils, they can survive in an anaerobic environment, such as clay soils. APB are capable of forming organic acids, such as acetic acids, which concentrate under the biofilm and as a result are very corrosive to carbon steel. There are other forms of APB that produce organic acids, such as sulfuric acid, or that produce carbon dioxide, which reacts with the water in the soil to produce carbonic acid.

However, the most aggressive attack of pipeline steels occurs when bacteria act cooperatively in communities to form complicated biofilms on the steel surface. Under these circumstances, anaerobic bacteria can survive in aerobic conditions if they are present in biofilms in which aerobic bacteria consume the oxygen.

Although the potential for MIC, to a large extent, is governed by the type of soil and the available nutrients, it has been suggested that even the process of trenching a pipeline can increase the levels of bacteria in the soil around the pipeline.<sup>20</sup> There are also other factors that will increase the susceptibility of a pipeline to MIC; indeed even measures designed to protect a pipeline from external corrosion can make it more susceptible to MIC if these measures fail. For example, the disbonding of the protective pipeline coating can produce an ideal microbial habitat, which is isolated from the effects of cathodic protection (CP). In fact, it has been shown that almost all cases of external MIC are associated with disbonded coating.<sup>24</sup> Some coatings are more prone to disbonding than others and therefore pipelines coated with these types of coating can be more at risk from MIC.<sup>23</sup> Coating types and failure mechanisms are discussed in detail in [Section 4.42.4.2.2](#).

#### 4.42.4.1.3 Preferential corrosion

Preferential (or selective) corrosion is predominantly found in pipelines manufactured prior to 1970, using a welding technique called low-frequency electrical resistance welding (LF-ERW). LF-ERW pipe is manufactured by forming a steel strip into a pipe and then simultaneously heating the edges of the strip using a low frequency alternating current and forcing the edges together under pressure. There are two problems associated with this type of pipe material: firstly, the pipe steel of the era could contain large amounts of nonmetallic inclusions due to high sulfur contents and secondly, the weld area was not always heat-treated and therefore could have inferior corrosion resistance and mechanical properties to the parent. As a result, the weld corrodes at a higher rate than the parent plate resulting in a V-shaped crack-like groove along the weld line in a region that tends to have properties inferior to those of the parent pipe material. There are two potential mechanisms by which preferential corrosion can occur in LF-ERW: by crevice corrosion at a lack of fusion defect and by dissimilar metal corrosion cells.

- *Crevice corrosion*

Surface-breaking lack of fusion defects in the weld are tight crevices that are open to the corrosive environment. Moisture becomes retained within the crevice and a local corrosion cell is formed. As a result, the crevice will corrode preferentially resulting in a groove-like defect at the weld line.

- *Dissimilar metal corrosion cell*

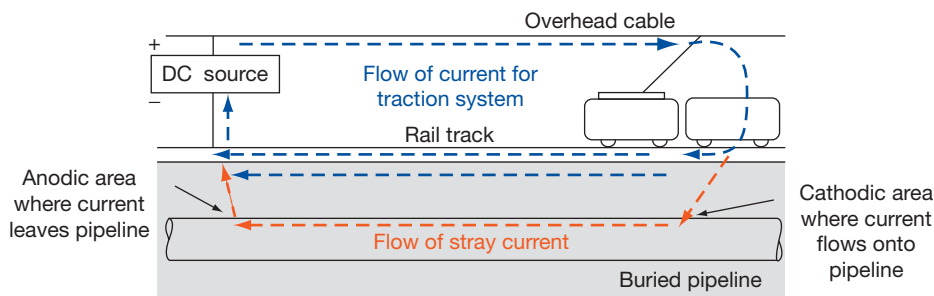

The other mechanism by which preferential corrosion can occur is the formation of a dissimilar metal corrosion cell at the surface. In ERW welds, the corrosion cell is set up between the weld material and the pipe body material due to chemical and physical property differences within the weld. The result is that the weld material becomes the anode in the

corrosion cell and will corrode preferentially, again resulting in sharp groove defects at the weld line.

#### 4.42.4.1.4 Stray-current corrosion

Another mechanism by which accelerated corrosion rates might be experienced on pipelines is stray-current corrosion. NACE defines stray-current corrosion as “corrosion resulting from the current through paths other than the intended circuit, for example, by any extraneous current in the earth.”<sup>22</sup> Direct currents can be present in the soil from electrified transport systems (e.g., railways or trams), CP systems for other pipelines, mining operations, high-voltage electricity transmissions systems, or even telluric currents caused by changes in the earth’s magnetic field. For an explanation of CP refer to [Section 4.42.4.2.8](#). In these systems, the earth provides part of the return path for the current to the source. However, any buried metallic structure in the vicinity, such as a pipeline, provides a favored, low-resistance path along which the currents can travel.

The mechanism for stray-current corrosion with reference to an electrified traction system is illustrated in [Figure 5](#). The return path for this system is provided by the rails; however, if the rails are not adequately insulated from the earth, some of the current will enter the ground and return via an earth path, unless a pipeline can provide a lower resistance return path. Where the current flows onto the pipe, the pipeline is cathodic and therefore protected as a result of the same process that applies in a CP system (see [Section 4.42.4.2.8](#)). The current travels along the pipeline and is discharged close to the source. At this point, the pipe is anodic and corrosion will occur at a rate that is dependent on the magnitude of the current flow, but may be many times greater than the soil corrosion rates.<sup>20</sup>

**Figure 5** Schematic of stray current corrosion from a railway system.

As a result, it is important that locations of suspected stray-current activity are identified and appropriate corrective actions implemented.

One of the problems with stray-current corrosion from electrified transport systems is that the current is dynamic or fluctuating, because the load varies with every train that passes. It is therefore important to identify the locations on a pipeline that may be at risk, that is, where the pipeline runs close to traction systems or where there may be locations of low track to earth resistance. In these areas, continuous monitoring for stray-current corrosion should be conducted over a 24-hour period to ensure that the time periods when the pipeline is at risk are identified. Stray currents from CP systems for other pipelines are termed static as they do not vary with time.

#### **4.42.4.1.5 AC corrosion**

The occurrence of pipeline corrosion as a result of direct current discharge (i.e., stray-current corrosion) is well recognized and accepted. However, there have also been reports of pipeline corrosion as a result of induced alternating current discharge. Although, the phenomenon of AC corrosion in soils is not fully understood and there is no agreement in the literature on the mechanism, it is possible to draw conclusions regarding the factors that make a pipeline susceptible to AC corrosion.

Pipelines at highest risk are those that run parallel to overhead AC power lines. The flow of current in the power lines produces an alternating magnetic field around the power line. If a pipeline is running within the magnetic field, then it is possible that an AC potential may be induced in the pipeline resulting in current flow. At points where the pipeline enters or leaves the magnetic field, the induced voltages are greatest. It is interesting to note that pipelines that cross at right angles to AC power lines do not have AC currents or voltages induced in them.

When a pipeline suffers from induced AC voltages, it has also been found that coatings with high dielectric strength, and therefore good insulators, will make the pipeline more susceptible to AC corrosion. The AC corrosion has been found to occur at small pinhole holidays in an otherwise good condition, adherent pipe coating. Another factor that makes a pipeline more susceptible is the resistivity of the soil. Low-resistivity soils in particular provide a more favorable route to earth for the current.

Corrosion caused by AC discharge occurs in the form of a small, deep hemispherical pits covered by a hard corrosion product. The current density at a

coating defect is one of the major factors influencing corrosion rate and is affected by the size of the defect, the soil resistivity, and the AC voltage on the pipeline. Initial work suggested that corrosion rates associated with AC corrosion were significantly lower than those caused by a direct current of a similar magnitude. However, corrosion rates of up to 10 mm year<sup>-1</sup> have been reported by pipeline operators.<sup>25</sup>

#### **4.42.4.2 External Corrosion: Prevention**

As described in previous sections, plain carbon steel is not resistant to corrosion from the external environment and therefore pipelines must be protected to prevent corrosion in the soil environment and a resulting loss of integrity. In general, underground pipelines are protected by the application of both an external coating and a CP system. These systems act synergistically to prevent external corrosion, the primary protection mechanism being the coating with the CP system designed to protect areas of the pipe where the coating becomes damaged. The next sections describe the features of the coatings and CP systems used to protect onshore pipelines.

##### **4.42.4.2.1 Requirements of pipeline coatings**

As described in [Section 4.42.4.1.1](#), for external corrosion to occur, two of the conditions that must be met are that the pipeline steel is immersed in a conducting electrolyte and that electrical current flow is permitted between the steel and the electrolyte. To prevent external corrosion therefore, the role of the pipeline coating is to provide a barrier between the soil and the steel to prevent moisture and oxygen contact with the pipe surface and also to act as an electrical insulator.

The construction of onshore pipelines involves welding together sections of pipe, generally 12 meters in length, in the field before lowering the completed pipeline section into the ditch. Historically the pipe spools were coated on site, 'over-the-ditch,' and although this practice is still used, the spools are more usually precoated in the pipe mill leaving a cutback area at the end of each spool to allow the field or girth weld to be made on site. This cutback area and the completed girth weld are then coated in the ditch. Two types of coating have therefore to be specified for the pipeline, the mill-applied main line coating and the field-applied girth weld coating.

In order for a material to be suitable as a pipeline coating, it must meet certain requirements, which are outlined in detail in the NACE recommended

practice RP0169.<sup>22</sup> The more critical requirements for the specification and selection of a pipeline coating can be summarized under the following general headings:

- *Adhesion*

As a primary role of the coating is to prevent water contact with the pipe surface, one of the critical requirements of a coating is that it should remain adherent to the steel for the design life of the pipeline. When a pipeline coating loses adhesion, water can enter beneath the coating and migrate along the pipeline between the pipe and the coating. One particular form of disbonding, termed 'tenting,' can occur along irregularities on the pipe surface, especially at long seam or girth welds. Coating disbonding is one of the most damaging modes of coating failure because, as will be described later, the area under the disbonded coating cannot be protected by the CP system. Although adhesion to the steel surface is dependent in part on the prolonged strength of the bond between the coating and the steel, it is also critically dependent on the surface preparation prior to the application of the coating. The surface of the steel must be adequately prepared to remove contaminants and also provide a suitable surface profile onto which the coating can attach.

- *Electrical resistivity*

Besides providing a barrier between the soil and the pipe steel, another critical function of the coating is that it should be an effective electrical insulator to prevent the flow of any corrosion current between the pipe and the soil. It is therefore important that the coating has a high electrical resistance (ER) that does not vary over time or with exposure to the environment as this will cause variation in the demand from the CP system.

- *Resistance to handling and construction damage*

If the coating is applied in the mill, then, before the pipeline is commissioned, there is the potential for the coating to be damaged at a number of stages, for example, during the handling and transportation of the linepipe to site, during manipulation for welding and laying operations, during the fabrication of cold field bends on site, and as a result of impact from rocks in the trench and backfill material. In order to minimize the extent of the coating damage, it is important that the coating has adequate flexibility as well as abrasion and impact resistance.

- *Compatibility with the pipeline environment*

For a buried pipeline, the coating selected for a particular application must be compatible with the

soil environment, and in particular, should not allow water to penetrate through the coating onto the steel surface. The coating must also be resistant to any other chemicals, for example, acids and alkalis, or microorganisms that may be found in the soil in which the pipeline is buried.

Another important factor associated with the pipeline environment is the operating temperature. If a coating is subject to temperatures outside the recommended maximum operating temperature, then this can result in disbonding, melting, creep, sagging, embrittlement, or softening of the coating. Ultimately, this will lead to the degradation of the coating and compromise the ability of the coating to protect the pipeline for the design life.

- *Compatibility with the CP system*

As the coating and CP system are acting together to protect the pipeline, it is important that the coating is not degraded by the CP system. One of the mechanisms by which this can happen is cathodic disbonding, a phenomenon by which accelerated disbonding can occur at the edge of a coating defect due to the action of the CP. Although the mechanism has not been fully characterized or understood, the major cause is thought to be chemical attack on the coating-steel bond by alkali generated by the cathodic electrochemical reaction:

Another effect of CP is that it can promote the permeation of water at the edge of a coating defect, which can also contribute to accelerated disbonding.

- *Resistance to in-service loads*

Once the pipe coating has been installed, the coating should be able to withstand any loads imposed during service. For example, it must be flexible enough to remain adherent to the pipe particularly during changes in internal pressure. However, the main external loading on the coating in service is as a result of soil loading and soil movement. Settlement of the backfill can create a tensile load on the pipe and cause creep of the coating. In addition, particularly in clay-type soils, the action of seasonal wetting and drying can lead to the expansion and contraction of the soil around the pipeline. As the soil moves, it can cause the coating to wrinkle and lose adhesion with the pipe. Soil movement around the pipe can also result from the creep of soil on slopes. In these types of soil environments, it is important to specify a coating with a high creep or shear resistance.

- *Compatibility with other coating systems*

Particularly for field joint or girth weld coatings, compatibility and adherence to the main line coating are especially important to prevent loss of adhesion around the girth welds. It is also essential that the coating is easy to repair if it becomes damaged.

Prior to specifying a coating for a pipeline, it is important that all of these factors are taken into account, and in particular, that the operating conditions of the pipeline, the location, that is, the local terrain and soil conditions, and the CP requirements are fully quantified and understood to ensure that the most appropriate pipeline coating is selected. NACE RP0169<sup>22</sup> identifies a series of tests that can be used to evaluate the suitability of a coating in the operating conditions.

#### 4.42.4.2.2 Types of pipeline coatings

The principal types of coating that are used for onshore pipelines are outlined in [Table 7](#).

Enamel-type coatings have been applied to pipelines for over 80 years, and consequently, they have been used to protect more pipelines around the world than any other coating. Coal tar coating systems consist of coal tar enamels, reinforced with felt or fiberglass wraps, which are applied hot over a primer of either chlorinated rubber or a two-component epoxy, depending on the service temperature requirements. One of the issues with the older coal tar systems was concern over the toxicity of the coal tar when heated. This led to the use of bitumen or asphalt coating

systems, which are applied in a similar way to coal tar systems but do not have the same health concerns.

In the 1950s, tape-wrap coating systems started to be used on pipelines and they remain a popular selection as they are readily available and easy to apply, either in the pipe mill or on site, and they tend to be a lower cost option. The first tape coatings were fabric reinforced petrolatum-based systems, but now there are a variety of systems available that can be applied either hot or cold. In general, a tape coating is a laminate system consisting of an outer backing material (e.g., polyethylene (PE), PVC, woven polyolefin) and an inner adhesive mastic (e.g., petrolatum grease, rubber-based compounds) that are spirally wrapped around the pipe ensuring a high degree of overlap between turns. Additional outer layers may be included for enhanced mechanical protection.

Mill-applied extruded polyolefin coatings were first introduced as pipeline coatings in the mid-1950s when PE was hot extruded onto small-diameter pipes over an asphalt mastic adhesive using a cross-head extruder. The process involved extruding a PE sheath onto a heated pipe coated in mastic, which shrank onto the pipe as it cooled. These two-layer PE-mastic adhesive systems were subsequently improved by replacing the asphalt mastic with butyl rubber or bitumen to provide better adhesion. Since the first extruded PE systems were used on pipelines, the number of layers, method of extrusion, type of mastic, and type of polyolefin have varied to improve the coating properties and the

range of pipeline sizes that may be coated with this system. The most recent developments were introduced in the 1980s with the use of three-layer PE and three-layer polypropylene (PP) systems with a fusion bonded epoxy (FBE) first layer. In these systems, the first layer of the coating is FBE, which is sprayed onto the heated pipe. The second layer is required to form either a mechanical or chemical bond between the FBE and the polyolefin and is either a copolymer or an adhesive-based material. The final layer is the extruded polyolefin; either PE (low, medium, or high density) or PP (for higher temperature operations). Although not the cheapest coating systems available, due to their enhanced properties, three-layer polyolefin FBE systems are one of the most widely used coating systems in Europe.

Besides its use in multilayer polyolefin systems, FBE is also applied on its own as a coating system. The coating consists of a partially reacted mixture of epoxy resin, curing agent, fillers, and pigments, which are dry-sprayed as a powder onto a heated pipe. The mixture then fuses and reacts to form a continuous epoxy film that cures under the action of heat. The system was first introduced in the mid-1950s but has only found application on large-diameter pipes since the mid-1970s. The superior properties of this type of coating, particularly with respect to soil stress and cathodic disbonding, make FBE one of the most popular pipeline coatings.

#### **4.42.4.2.3 Types of field joint coatings**

All of the coatings described in [Section 4.42.4.2.2](#), except the extruded polyolefin systems, can also be applied in the field to the girth weld joints. However, there are also some coating systems that were specifically designed for the field joint.

One of the field joint systems that has been in use since the 1960s is heat-shrinkable sleeves. As the name implies, these coatings consist of a polymer sleeve that is shrunk onto the pipe joint, either over a mastic adhesive or an epoxy primer, by the application of heat. It is important that the coating is heated correctly when applying heat-shrinkable materials as too little heat can mean that the adhesive fails to flow and therefore the coating loses adhesion, although too much heat can damage the sleeve and main pipe coating.

Liquid coating systems, such as two-pack epoxies or two-pack urethanes, were developed to be compatible with FBE coatings, both for field joints and for repair. The systems consist of two components, a base resin and a hardener, which are combined together

before application either by brush, trowel, or spray. It is critical that the components are correctly mixed as otherwise the coating will not cure properly.

#### **4.42.4.2.4 Coating failure**

Even after specifying the requirements of a coating for a particular service, conducting laboratory or field testing and selecting the most appropriate coating for the pipeline and field joints, coating damage must still be expected on buried pipeline systems and it is impossible to maintain the coating in a damage-free condition. Some of the damage mechanisms have been discussed in [Section 4.42.4.2.1](#) and include the disbonding of the coating, rock damage during installation and service, handling and construction damage, soil loading, and degradation due to environmental and temperature effects. However, many pipeline coating failures can often be attributed to either incorrect application of the coating or incorrect specification.

- *Incorrect specification*

There is no standard method for selecting a coating for a particular service, and although laboratory or field test results are useful, they will not fully predict the long-term performance of a particular coating system. Therefore, the decision on which coating system to choose is not straightforward. It has also to be recognized that the cost of the coating system is not an insignificant factor in coating selection and can be particularly significant when coating a pipeline of hundreds of kilometers. Selection can therefore be a balance between long-term performance of the coating and cost.

- *Incorrect application*

Even if the most suitable coating material is selected, poor preparation and application will lead to premature failure. It is therefore essential that rigorous procedures are specified for each stage of the pipeline coating process, not only for surface preparation and application but also for repair and testing of the coating. As mentioned previously, adhesion to the steel substrate is one of the most important factors in the performance of pipeline coatings. Most coating systems rely on a clean, properly prepared surface to develop and maintain maximum adhesion to the pipeline. Poor surface preparation can either lead to contamination being left on the pipe surface or the incorrect surface finish being achieved to promote a good bond between the pipe surface and coating. This can result in a rapid loss of adhesion and coating deterioration during service.

Once the surface has been prepared, the coating needs to be applied in accordance with appropriate specifications and the process monitored with quality standards that are regularly checked. Poor coating application often results when the specification program is inadequate or the applicator does not adhere to the correct procedures in the program. It cannot therefore be overemphasized that it is only through attention to the whole coating process that maximum coating performance can be maintained throughout the design life of the pipeline.

#### **4.42.4.2.5 Coating condition monitoring**

It is recognized that the coating system on buried pipelines cannot be maintained in a 100% defect-free condition. Not only can handling during construction cause damage to coatings but also soil movements and soil stresses may cause subsequent damage to coating systems after they are installed. It is a fact that all coating systems will eventually show some degradation with time. Although defects in a coating are intended to be protected by the CP system, if a coating holiday is large enough or if there are too many coating holidays on the pipeline, the current required to protect the total bare area of steel may exceed the capacity of the CP system. Therefore, understanding the condition of the coating during pipeline operation is an important part of maintaining corrosion protection on the pipeline. There are a number of techniques that can be used to evaluate the condition of the coating that do not require random excavation and visual inspection. These coating defect survey techniques can identify the location of holidays, and in ideal conditions, can give an indication of relative coating size. The measurements are taken through the soil layer by walking above the pipeline and are therefore referred to as above-ground surveys.

One of the property requirements of the pipeline coating that was discussed in [Section 4.42.4.2.1](#) was good electrical insulation. Therefore, if the coating is maintained in a defect-free condition and an electrical current is applied onto the pipe, no leakage of that current should occur unless there is a hole in the coating. Where there is a hole in the coating, any applied current will leak out into the surrounding soil. This is the principle on which the coating defect inspection techniques that are used on pipelines are based; the detection of the effects of an applied current leakage is either achieved through measuring the reduction in current flow ahead of the holiday or by measuring the potential gradient in the soil caused by the flowing current.

The above-ground survey techniques can be grouped on the basis of the type of current that is applied to the pipeline to detect the holiday, that is, AC or DC. In this chapter, a brief description is given of some of the main methods in these categories. However, more information on different survey techniques can be found in Appendix A of NACE RP0502.<sup>44</sup> It should be emphasized that the above-ground survey techniques will not find disbonded coatings. In this situation, the hole in the coating may be very small and does not relate to the size of the corroding area under the disbonded coating.

#### **4.42.4.2.6 Coating condition monitoring: DC methods**

The current required for DC methods is already available on the pipeline from the CP system, although the current may have to be increased in order to ensure that the potential gradients created at coating defects are more measurable. If the CP current cannot be changed or interrupted, the current can be obtained from a temporary supply. Although the ability to use the CP current is an advantage, it also means that these survey techniques cannot be conducted at the same time as a CP monitoring survey, as the enhanced current requirements will not represent the normal working conditions of the CP system.

- **Analog Direct Current Voltage Gradient (DCVG)**

In a DCVG survey, the CP current is switched on and off at a frequency of  $\sim 1$  Hz and the resulting voltage gradient created at coating defects is measured between two earth contact probes that are carried by a single operator. The two probes are calibrated at the start of the survey by ensuring that no difference in potential is registered when the probes lie on the same equipotential line. To understand how the survey is conducted, imagine lines of potential around a coating defect ([Figure 6](#)). As the operator approaches the defect, a potential difference will be recorded between the two probes. The direction of voltage swing will indicate the location of the defect center. When the operator is directly above the defect, no swing in potential is recorded and therefore the location of the defect is identified.

One of the advantages of DCVG is that it is also able to give an indication of the size of the coating defect. To do this, one probe is positioned directly above the defect and the other is moved out to one side at right angles to the flow direction of the pipeline. The operator records the potential difference between the probes and continues to move away from

**Figure 6** Potential fields surrounding a coating defect in the analog DCVG technique.

the pipeline until no further detectable potential shift is noted. At this point, the probes are considered to be outside the field of significant current flow and in a remote earth potential zone where there is no significant current flow through the earth. The total potential gradient to remote earth is a measure of the size of the defect at that location. This value is usually divided by the difference between the pipe-to-soil ON and OFF potentials (for an explanation of these terms refer to [Section 4.42.4.2.14](#)) at that point to provide a benchmark measure of the size of the defect. This is referred to as the %IR reading and the larger the %IR value the larger the coating defect. DCVG survey readings are reported in four categories depending on the magnitude of the measured %IR, and the recommendations regarding remediation requirements are based on the %IR reading.

The main disadvantage of the DCVG method is that electric fields can be distorted by adjacent uncoated foreign structures, which can make data interpretation very difficult. In addition, it should be emphasized that the size of the coating defect is not an indication of the potential size of the underlying corrosion defect, that is, deep pits could be located under small coating holidays. In addition, a good contact with the soil has to be maintained with this technique. Consequently the DCVG survey method

is not easy to use in built-up areas where the pipeline route may be surfaced.

#### **4.42.4.2.7 Coating condition monitoring: AC methods**

In AC methods, the current is applied via a transmitter. The advantage of an AC method is that, as the method does not use the CP current, it can be conducted at the same time as a CP survey (see [Section 4.42.4.2.15](#).) However, AC signals can also be generated from other sources in the vicinity of the pipeline, such as overhead power cables, a phenomenon that was discussed in [Section 4.42.4.1.5](#). The effect of these AC signals on the readings can be overcome by using filters and by selecting an appropriate signal frequency for the survey.

##### **• Pearson surveys**

Pearson testing was one of the first types of holiday testing developed for buried pipelines. The technique employs two operators who are connected together by a wire and make an earth contact with the ground either using boots with metal cleats on them or with metal-spiked poles. The change in potential difference between the operators as they pass over a defect locates the defect on the pipeline and this is recorded by a receiver/data logger that is carried by the lead

operator. As with DCVG, one of the problems with Pearson testing is that a good contact with the soil must be maintained. In addition, detection can be difficult in high-resistivity soils as the current leakage detectable at the surface will be small.

- *AC current attenuation*

In this method, an AC current is applied to the pipeline via a signal generator that is generally connected at a CP rectifier. The resultant electromagnetic field generated around the pipeline is measured by an operator carrying a receiving unit. The principle of operation is that when a signal is applied to a coated buried pipeline, it will gradually decay away from the point of application. The rate of decline (attenuation) is a measure of the average coating condition between two given points. In general, the survey is first conducted on a macro scale (e.g., every kilometer) to identify sections of poor coating and then on a finer scale in specific areas (e.g., every meter) to pinpoint larger coating defects. One of the advantages of this method is that it does not require soil contact and can be conducted over any surface that will allow transmission of the electromagnetic field, for example, ice, water, or concrete. It is also possible to use the same equipment to locate the pipeline and provide a reading of the depth of burial of the pipeline in the same survey.

#### 4.42.4.2.8 Cathodic protection (CP)

Although a pipeline coating is specified to last for the design life of the pipeline, it has been shown that it is impossible to maintain a coating in a defect-free condition. Where there are defects in the coating, and therefore where there are areas where the steel is exposed to the soil environment and current can flow, the pipeline can corrode. To protect these areas from corrosion, a CP system is also installed on the pipeline.

Remembering the half-cell reactions for the corrosion of steel in the soil environment from [Section 4.42.4.1.1](#), corrosion, or the dissolution of iron, occurs at the anode where current leaves the pipe surface. The principle of CP is therefore to reduce the current flow away from the pipeline at these points by imposing a direct current onto the pipeline so that it becomes the cathode in the corrosion cell and does not corrode. Of course, in principle, it is possible to protect a pipeline using CP alone. However, the current required to achieve protection makes this unfeasible, which is why the combination of coatings and CP is the most practical method for protecting a pipeline from external corrosion.

Two main methods of CP are used in onshore pipelines: the galvanic, sacrificial anode method and the impressed current method.

#### 4.42.4.2.9 CP: Sacrificial anode systems

The principle of the sacrificial anode method is to make the pipeline the cathode in the corrosion cell by connecting it to an anode material that is more electronegative than steel in the electromotive series. Thus, current will flow from the corroding ‘anode,’ typically magnesium, zinc, aluminum, or alloys of these materials, to the pipeline ‘cathode’ through the soil. At locations where there are holidays in the coating, the current can flow onto the pipeline and repress the anodic reaction. The return path is provided by thermit welding a cable connection to the pipeline ([Figure 7](#)).

The advantage of the sacrificial anode system is that no external power source is required and therefore the system is easy to install and requires minimal maintenance. However, one of the main disadvantages of this type of CP system is that the available current is fixed and the driving potential between the steel and the anode material is limited by their separation in the electromotive series. In order to maximize the available current, these systems are therefore most effective in low-resistance soil environments. The limited current availability of this system also means that to protect long lengths of pipe, particularly poorly coated or bare pipe, requires large numbers of anodes to ensure that sufficient current is provided to the pipeline. The sacrificial anode system is therefore often used onshore to protect small areas of pipeline at specific critical locations. Another main disadvantage of a sacrificial anode system is that the anodes are consumed over time and therefore have a finite life after which they have to be replaced.

**Figure 7** Schematic of the sacrificial anode cathodic protection system.

**Figure 8** Schematic of the impressed current cathodic protection system.

#### 4.42.4.2.10 CP: Impressed current systems

In an impressed current system, the protection current is supplied by connecting the negative terminal of an external power supply to the pipeline and the positive terminal to an inert anode (Figure 8). The system therefore consists of an AC source, which is rectified to produce a DC output, a groundbed of anodes, and wires connecting the anodes and the pipeline to the rectifier. Current flows from the anode groundbed through the soil to the pipeline and returns via the thermit-welded CP connection. The anodes that are used for the protection of pipelines are generally high-silicon chromium cast iron or mixed metal oxide coated titanium, buried in a coke-filled groundbed, to provide a low-resistance path for the current into the soil.

The main advantage of the impressed current system over the sacrificial anode system is that a larger driving potential is available and the voltage and current can be controlled. This makes the system more adaptable to the changing current levels required to protect the pipeline as it ages and the coating deteriorates and also more adaptable for use in high-resistivity soils. However, this system does require an external power supply and therefore has an associated ongoing through-life cost, and in addition, also requires more frequent maintenance and inspection than a sacrificial anode system.

#### 4.42.4.2.11 Basic CP design

Although the subject of CP design is addressed in international standards and guidance, several key factors need to be considered when installing a CP

system to ensure that the pipeline is adequately protected from external corrosion.

One of the critical requirements is ensuring that enough current is supplied to the pipeline to protect areas of coating damage. The larger the area of coating damage, the larger the current required to achieve a sufficiently high current density to ensure that the pipeline is protected. Other factors that need to be addressed are the type of CP system to be used (i.e., sacrificial anode or impressed current) and the spacing of the anodes along the pipeline to ensure that the required current levels are achieved at locations remote from the anode or power supply. These decisions will require knowledge of the pipeline environment including the soil resistivity, the coating type, the location of other metallic structures that could interfere with the CP current, and the presence of sources of stray current. In this respect, one of the features of the CP design includes the location of isolation joints. These joints are used to insulate the pipeline from current paths that could take current away from the pipeline and therefore reduce the level of protection. Isolation joints are therefore located at above-ground facilities such as terminals, pumping stations, offtakes, and instrument lines. They can also be used to control stray currents by electrically separating sections of pipeline.

The CP system must also be designed in such a way that it can be easily monitored and therefore test points are installed along the pipeline at intervals that are dependent on the location of the pipeline. An ideal spacing is every one to two kilometers, although often test points are located close to road crossings for ease of access and convenience. The test point consists of a wire connection from the pipeline to a test box that is usually located above ground so that measurements of current and voltage can be made to confirm that the pipeline is adequately protected. Additional test points are also located at other critical locations, for example, crossings, sources of external current (i.e., traction systems), and isolation joints.

#### 4.42.4.2.12 CP requirements

In order for CP to be effective, the current supplied to the pipeline must shift the potential at that pipe surface sufficiently negative such that the surface becomes the cathode in the corrosion cell and the anodic reactions are reduced or suppressed. Therefore, in order to ensure that the pipeline is protected to a level that will stop significant corrosion, it is necessary to set criteria for monitoring a pipeline to ensure that the protection levels are achieved. In this

respect, the current supplied is not a reliable measure of protection, as it can change with time and therefore protection criteria are based on a measure of the potential difference between the pipe and the soil as measured against a copper–copper sulfate reference electrode.

Both ISO 15589<sup>26</sup> and prEN 14919-1<sup>27</sup> state that for onshore buried pipelines, all parts of the pipeline should be polarized to a potential more negative than  $-850$  mV. This is the most widely accepted and common criterion and indicates that protection is achieved if the potential of the structure is more negative than  $-850$  mV when measured with a copper–copper sulfate reference electrode. The criterion is increased to  $-950$  mV if active bacterial or anaerobic conditions are suspected and can also be adjusted to account for low resistivity-soils or high temperature operation.

Another criterion that can be applied, typically to pipelines that have poor or aging coating systems, is the 100 mV polarization shift criterion. This criterion states that protection is achieved if the polarized potential is shifted at least 100 mV in the cathodic direction below the natural corrosion potential as illustrated in the schematic Evans Diagram of [Figure 9](#). Although this criterion may be easier and cheaper to achieve than the  $-850$  mV criterion for some pipeline systems, in order to apply the criterion successfully, a detailed characterization of the environment around the pipeline is required. In particular, this criterion should be avoided in anaerobic soils, where SRB activity is expected, or in regions affected

by interference currents or stray currents. In these types of environments, the 100 mV shift may not be sufficient to reduce the corrosion rate to acceptable levels and could result in the pipeline being in the critical range for high-pH SCC (see [Section 4.42.6.1.1](#)).

#### 4.42.4.2.13 CP shielding

In a discussion on CP effectiveness on pipelines, the subject of CP shielding should be included, as this phenomenon reduces the effectiveness of the CP and can cause a serious problem with respect to the detection of corrosion. Shielding in effect reduces the current flow to the pipeline, although measurements taken above the surface will indicate that the pipeline is still protected. The most common shielding situations are pipelines installed within a bare steel casing with the casing short-circuited to the pipe and pipelines under a disbonded coating. The latter situation was introduced in [Section 4.42.4.2.1](#) when coating adhesion was highlighted as a major requirement for a pipeline coating. When the coating becomes disbonded, sufficient CP may not be able to penetrate to the area of corrosion under the coating and protect the pipeline from corrosion.

#### 4.42.4.2.14 CP monitoring

To make sure that cathodic protection is achieved and continues to be achieved, the CP system should be regularly monitored. There are two levels of monitoring: regular equipment checks to ensure that the systems are operating and less regular surveys at fixed test points to ensure that protection is being achieved. These surveys involve measuring the pipe potential at every test point and then carrying out further surveys between test points and remedial action if the readings show inadequate protection.

However, before looking at the survey techniques, an initial explanation of pipeline potential measurements is required. There are essentially three potential measurements that can be made on a pipeline; the natural potential, the ON potential, and the OFF potential.

- *Natural potential*

The natural potential of the pipeline is the potential of the corroding pipeline with no protection current applied. Ideally, the natural potential should be measured before any current is applied to the pipeline either from a CP system or by the action of stray

**Figure 9** Schematic Evans diagram illustrating the principle of the 100 mV CP criterion.

currents as these alter the natural current balance, which can then take weeks or months to recover. A reading of natural potential is required if the pipeline is going to be protected using the 100 mV shift criterion (see [Section 4.42.4.2.12](#)).

- *ON potential*

An ON potential reading is the potential measured on a pipeline at the above-ground surface once a CP current has been applied. The reading does not necessarily imply that CP has been achieved because of the errors that occur in the readings of CP and how they are taken. In effect, the measurement of potential on the surface above the pipeline with the CP system on is made up of two components as shown in the following equation:

$$V_s = V_p + V_{IR}$$

Where  $V_s$  is the measured potential at the surface,  $V_p$  is the actual potential at the pipe, and  $V_{IR}$ , sometimes termed the IR drop, is the potential drop associated with the flow of CP current through the soil of finite resistance and onto the pipeline. Therefore, although  $V_p$  is the reading that is required to determine whether CP criteria have been achieved on a pipeline, an ON potential reading is measuring  $V_s$ , which includes the IR drop. Therefore an ON potential reading will overestimate the level of CP on a pipeline, but if IR drops are known to be low, then it can provide an estimate of the amount of protection.

- *Instant OFF potentials*

One method adopted for assessing the true potential without the IR component is what is termed the Instant OFF polarized potential. This test is carried out by switching the CP system off and monitoring the potential of the structure before the potential has begun to decay significantly. There is no current flowing through the soil to the defect and thus the IR component or error in the potential reading will, for practical purposes, be almost eliminated.

#### **4.42.4.2.15 CP Monitoring: Close interval potential (CIPS or CIS) surveys**

This technique involves measuring ON and OFF potentials at close intervals over a pipeline, and hence, the method is often called a CIPS survey or close interval survey (CIS). The CP current is switched ON and OFF by inserting a timer switch at the rectifier and the switching cycle is set up so that the ON cycle is longer than the OFF cycle, by a typical ratio of 5:1, to avoid significant decay of the potential. The survey is conducted by attaching a

spool of very fine insulated wire to a pipeline test point terminal and connecting this to a test meter and a copper/copper sulfate half-cell, which is located in a pole that is carried by the operator. The survey operator then walks along the pipeline route taking ON and OFF potential readings with the half-cell, approximately every meter along the pipeline. Often two half-cells are used so that one is always in contact with the ground. Although ON and OFF potentials may be routinely measured at test posts, this type of survey allows the potential to be measured between test posts and can determine whether the pipeline is adequately protected along its length.

A CIPS or CIS survey is generally used to measure the effectiveness of the CP system, although it can also be used to locate coating defects using the same principle as the DC methods described in [Section 4.42.4.2.6](#). The basis of this technique is that a dip in the ON and OFF potential profiles along the pipeline provides an indication of the presence of a coating defect due to the loss of protection at that point.

#### **4.42.4.3 Assessing the External Corrosion Risk**

The preceding sections have served to outline the causes of external corrosion on buried pipelines and to describe how external corrosion is prevented and controlled. The knowledge of how and why external corrosion occurs also aids in identifying the key factors that are used in risk assessment strategies for external corrosion. On the basis of this review, a summary list of typical data that are required to assess the threat of external corrosion is presented in [Table 8](#). It can be seen that this list includes not only information about the environment of the pipeline but also information about how the pipeline is maintained in terms of the coating condition and the effectiveness of the CP. All these factors are then fed into the types of algorithms described in [Section 4.42.3](#) to rank the relative risk of external corrosion on the pipeline.

#### **4.42.5 Internal Pipeline Corrosion Risks**

The scope of this chapter has been limited to an investigation of corrosion in onshore gas and liquid transmission and gathering pipelines. For external corrosion, the type of pipeline, that is, transmission or gathering, is less relevant in determining whether

**Table 8** Summary of typical information required to assess the external corrosion threat

	<i>Data required to assess threat</i>	<i>Comment</i>
<i>Pipeline characteristics</i>	Age of pipeline Type of pipe	Could highlight a susceptibility to certain forms of corrosion (e.g., preferential corrosion).
<i>Coating information</i>	Coating type  Coating condition	Indicates the likely modes of coating failure and corrosion damage, for example, disbonding. Could either be a subjective view (i.e., good, average, poor, etc.) or a more quantitative measure gathered from coating monitoring surveys.
<i>CP information</i>	CP availability CP protection levels	Indicates the likelihood that damaged areas of coating are not protected. Could be subjective or determined from CP monitoring surveys.
<i>Pipeline environment</i>	Soil characteristics  Evidence of MIC  Potential sources of stray currents Potential sources of AC corrosion	Indicates the corrosivity of the soil and would include the type of soil as a minimum but could also include more detailed resistivity data, pH, bacterial levels. Usually evidence gathered during direct inspection although could also be implied from soil conditions. Would include data such as proximity of other pipelines, structures, rail crossings For example, proximity of overhead power lines
<i>Pipeline history</i>	Leak history Previous inspection reports	Provides more quantitative evidence of a corrosion threat

the pipeline will be susceptible to external corrosion. However, the type of pipeline becomes more significant when considering the threat of internal corrosion. Gathering systems are generally collecting product from a wellhead and transporting it to a processing plant or transmission pipeline. The fluid is not processed before it enters the gathering system and therefore the product can contain contaminants that increase the susceptibility to internal corrosion. However, the product in a transmission pipeline will have undergone basic or full product processing and therefore the internal corrosion threat is more controllable.

It should be highlighted at this stage that dry natural gas and moisture-free oil and petroleum products are not corrosive to carbon steel. It is only in the presence of water and contaminants such as chlorides, CO<sub>2</sub>, H<sub>2</sub>S, organic acids, bacteria, and oxygen that corrosion will occur. Internal corrosion of pipelines is generally classified as either sweet or sour depending on the level of H<sub>2</sub>S in the product.

#### 4.42.5.1 Sweet or CO<sub>2</sub> Corrosion

Sweet corrosion of carbon steel occurs in the presence of free water that has been acidified by carbon dioxide present in the oil or gas. It is therefore important to note that sweet corrosion will not

occur in the pipeline if free water is not present in the product, that is, dry CO<sub>2</sub> gas does not pose a corrosion threat to pipeline steel. Water in the pipeline can be present from different sources, depending on whether the pipeline is in the gathering or transmission system and what processing has been carried out.

In the gathering system, the pipeline is transporting product directly from the reservoir generally without any pretreatment. Therefore, water that is naturally present in the gas phase or water present in the rock pores, which is then mobilized with the oil or gas (formation water), can be present in the pipeline. Once the product has been processed, it is still possible for water to enter the transmission pipeline either as a result of water carryover from the separators or due to water dropping out or condensing from the product. Water drop out occurs in oil pipelines if water is entrained in the oil as an emulsion. During transport through the pipeline, the water can separate out of the emulsion as a distinct phase at the bottom of the pipeline. In gas pipelines, water can condense out of the gas phase (condensed water) if the temperature of the steel surface falls below the dew point of the gas. This type of corrosion is sometimes termed top-of-line (TOL) corrosion and tends to be a particular issue for subsea pipelines where exposed sections of the pipeline can be cooled by the sea.

The mechanism of CO<sub>2</sub> corrosion is complicated,<sup>28</sup> but initially the CO<sub>2</sub> gas dissolves in water to form carbonic acid according to the equation:

The carbonic acid then reacts with the steel according to the following reaction to produce iron carbonate and hydrogen.

Under favorable conditions, the iron carbonate can form a protective or semiprotective scale on the pipeline surface. It is the presence and stability of this film that determines the rate of general corrosion and can also dictate the susceptibility to localized attack by mechanisms such as pitting corrosion, preferential weld corrosion, and flow-induced localized corrosion (FILC).

Schmitt and Hörstemeier<sup>29</sup> have reviewed the parameters that influence the CO<sub>2</sub> corrosion mechanism and have concluded that the factors affecting the rate and nature of the CO<sub>2</sub> corrosion reaction can be divided into three categories: interface-related parameters (temperature, flow rate, condensation, and presence of scales), materials-related parameters (alloy composition, microstructure, and heat treatment) and medium-related parameters (pH, CO<sub>2</sub> partial pressure, solution chemistry, and oxygen content). The key parameters in this list are worthy of further discussion in relation to the factors that affect internal pipeline corrosion.

#### 4.42.5.1.1 Effect of temperature

Below 60 °C and at low levels of pH, the solubility of iron carbonate is high and the formation of a stable FeCO<sub>3</sub> film on the pipe surface is difficult. The rate of the reaction is controlled by the dissolution of iron and increases with increasing temperature. Above 60–80 °C, the solubility of iron carbonate decreases, allowing the formation of a more adherent, semiprotective scale of FeCO<sub>3</sub> on the surface and an overall reduction in the corrosion rate. It should be noted, however, that in order for the FeCO<sub>3</sub> scale to be effective in reducing corrosion rates, it must be adherent and cover the whole pipe surface. If the scale becomes damaged, for example, as a result of turbulent flow, then corrosion of the unprotected steel can occur at high rates. This gives rise to a particular type of localized corrosion called mesa corrosion, which is described in more detail in [Section 4.42.5.2.2](#).

#### 4.42.5.1.2 Effect of flow rate

As already mentioned, the corrosion rate for CO<sub>2</sub> corrosion is dependent on the ability of the system to establish and maintain a stable iron carbonate scale on the steel surface. If the flow velocity is greater than a certain critical value, then it is possible that the scale can be eroded by the turbulent conditions near the pipe wall. Under such flow conditions, the scale is unable to reform, resulting in unprotected areas of the pipe and therefore increased corrosion rates.

The flow rate can also affect the distribution of corrosion. As discussed previously, in oil pipelines it is possible that water is carried over into the pipeline entrained in an emulsion. In low-velocity or nonturbulent flow, the water will separate out of the emulsion and collect in pools, particularly at low points in the pipeline.

#### 4.42.5.1.3 Effect of pH

In general, the corrosion rate for CO<sub>2</sub> corrosion decreases as the pH increases. The pH is dependent on the type of free water present in the pipeline, that is, whether it is condensed water or formation water. Condensed water is relatively pure and therefore the pH is determined by the partial pressure of CO<sub>2</sub>; the higher the CO<sub>2</sub> concentration, the more acidic the water and the lower the pH. However, as the pipeline corrodes, the condensed water will become saturated with carbonate from the corrosion product and the pH will rise with a consequent reduction in the corrosion rate. Although the concentration of CO<sub>2</sub> in the product will also affect the pH of formation water, ionic species present in the rocks, (e.g., bicarbonate, chlorides, sulfates, etc.), which are in solution in the water, also influence the pH.

Another impact of the pH on sweet corrosion is that, as the pH of the water is increased, the solubility of iron carbonate is reduced and therefore the deposition of the protective scale on the steel surface becomes more favorable. This effect also reduces the corrosion rate.

#### 4.42.5.1.4 Effect of partial pressure of CO<sub>2</sub>

As the sweet corrosion reaction involves the dissolution of CO<sub>2</sub> in water to produce carbonic acid, the concentration of the acid produced is directly related to the concentration of CO<sub>2</sub> in the gas and therefore to the partial pressure of CO<sub>2</sub>. Consequently, the reaction rate will increase as the CO<sub>2</sub> partial pressure increases producing higher concentrations of carbonic acid and reducing the solution pH.

#### 4.42.5.1.5 Effect of H<sub>2</sub>S content

H<sub>2</sub>S can be present naturally in the reservoir or can be produced during the extraction process. The influence of small amounts of H<sub>2</sub>S (i.e., <0.0035 bar partial pressure H<sub>2</sub>S) on CO<sub>2</sub> corrosion is dependent on the concentration of H<sub>2</sub>S and whether iron sulfide can precipitate as a protective surface scale. At low concentrations of H<sub>2</sub>S and low values of pH, when iron sulfide precipitation does not occur, the experimental evidence is confusing and the mechanism by which H<sub>2</sub>S affects the corrosion rate is not well understood. For example, some studies indicate that the corrosion rate is increased compared with an equivalent H<sub>2</sub>S-free CO<sub>2</sub> corrosion environment,<sup>30</sup> while others suggest that small amounts of H<sub>2</sub>S could reduce the corrosion rate.<sup>31</sup>

As the H<sub>2</sub>S concentration increases the formation of the iron sulfide surface film becomes more favorable. The exact composition of the surface scale in slightly sour conditions is dependent on the CO<sub>2</sub>–H<sub>2</sub>S ratio. Iron sulfide scales are conductive and therefore make very efficient cathodes. However, if the scale becomes damaged, then small anodic areas can form, which can result in high pitting corrosion rates. At higher concentrations of H<sub>2</sub>S, that is, greater than 0.0035 bar partial pressure H<sub>2</sub>S, the mechanism of corrosion changes from one of general or pitting corrosion to cracking, and the product is termed sour. Sour cracking is discussed in more detail in [Section 4.42.5.3](#).

#### 4.42.5.2 CO<sub>2</sub> Corrosion – Localized Effects

The general corrosion rate for sweet corrosion is principally determined by the establishment of a scale of either iron carbonate or iron sulfide (depending on the H<sub>2</sub>S content) on the surface of the pipe. If this scale is not uniform or becomes damaged (e.g., due to erosion, shear stresses in the scale, scratching, or mechanical damage), then the underlying steel is locally unprotected and the pipeline becomes susceptible to localized attack. Particular forms of localized attack that are found in pipelines include pitting corrosion, mesa corrosion, FILC, and preferential corrosion.

##### 4.42.5.2.1 Pitting corrosion

The susceptibility of the pipeline steel to pitting corrosion increases with increasing temperature. As discussed previously, below 60 °C, the iron carbonate scale is thin and the protection that it provides to the steel is low. However, the scale becomes more stable

and adherent above 60 °C, and therefore, a reduction in corrosion rate is observed for general corrosion. However, if the scale becomes locally damaged, the steel is unprotected and CO<sub>2</sub> corrosion can occur at high rates, due to the increased temperature. It is therefore possible to observe localized pitting damage in pipelines operating above 60 °C.

##### 4.42.5.2.2 Mesa corrosion

Mesa corrosion is a form of CO<sub>2</sub> corrosion that occurs under conditions of high temperature (above 60–80 °C) and under enhanced flow rates. The morphology of the attack is characterized by steep-sided transitions from uncorroded to corroded areas similar to mesa formations in rocks. Mesa corrosion results from flow-induced spalling of the carbonate film due to internal stresses developed in the scale during its formation. The underlying, unprotected metal is then exposed and corrosion occurs at rates of up to several mm year<sup>-1</sup>, resulting in the formation of deep flat-bottomed, sharp-edged pits.<sup>29</sup> As a higher temperature is required than is normal for transmission pipelines, mesa corrosion is mainly found in gathering systems.

##### 4.42.5.2.3 Flow-induced localized corrosion (FILC)

FILC occurs in pipelines under conditions of local turbulence where the carbonate scale cannot reform. FILC is normally initiated at locations where the scale becomes cracked or spalled by the action of hydrodynamic forces induced by the local flow conditions. In order to fracture the scale, the hydrodynamic force must exceed the fracture stress of the scale. There is still debate in the literature with regard to the best way to quantify the hydrodynamic forces and therefore to determine the critical parameters under which FILC occurs.<sup>29</sup>

##### 4.42.5.2.4 Preferential weld corrosion

Another localized corrosion effect that has been observed in pipelines is preferential weld corrosion. It can occur at welded joints if a galvanic couple is established between the parent pipe and the weld heat-affected zone (HAZ) or weld metal due to local differences in composition. The susceptibility of a pipeline to preferential weld corrosion and the location and morphology of the corrosion are dependent on the environment (in terms of the nature of the scale that is formed); the microstructure and composition of the steel and the weld (in terms of the establishment of the galvanic couple and the general corrosion resistance of the material); and

local geometry effects (in terms of the establishment of regions of local turbulence). In terms of the corrosion theory, preferential weld corrosion occurs because the weld or HAZ material becomes anodic with respect to the parent material. Solutions to prevent this form of corrosion are therefore aimed at adding elements such as Cr, Ni, and Cu to the weld metal to make the weld more cathodic with respect to the parent.

#### 4.42.5.3 Sour Corrosion

The effect of low levels of  $H_2S$  on internal pipeline corrosion was described in [Section 4.42.5.1.5](#). In this section, a partial pressure of  $H_2S$  of 0.003 5 bar was defined as a threshold above which sour corrosion cracking mechanisms would dominate over sweet corrosion mechanisms. This limit has been defined in the standard NACE MR0175/ISO15156-2<sup>32</sup> and is presented in the form of a domain diagram that indicates the susceptibility to sour cracking on the basis of the local pH and partial pressure of  $H_2S$ . The diagram is divided into four domain areas; in domain zero, there is low risk from sour corrosion. However, as the partial pressure increases above 0.003 5 bar, decreasing the pH and/or increasing the pressure increases the severity of sour service damage from domain one (mild sour service) to domain three (severe sour service). It is critical that the susceptibility of a pipeline to sour service cracking is understood and quantified at the design stage as material choices have to be made to prevent rapid pipeline failure. Failure times as short as days or hours have been observed for sour corrosion mechanisms under test conditions. Material selection for sour service is discussed in [Section 4.42.5.4](#).

The principal mechanism of sour corrosion is hydrogen damage and the role of  $H_2S$  is to promote the penetration of atomic hydrogen, produced at the cathode, into the steel. As with sweet corrosion, sour corrosion mechanisms also require a source of water. When hydrogen diffuses into the steel matrix, it can either remain in solution in the steel lattice (hydrogen embrittlement) or recombine to form hydrogen gas (internal hydrogen pressure). The defects that are characteristic of sour service result from one of these two mechanisms; hydrogen embrittlement results in sulfide stress corrosion cracking (SSCC), whereas internal hydrogen pressure can result in hydrogen-induced cracking (HIC). Stress-orientated hydrogen-induced cracking (SOHIC) is thought to occur by a combination of the two mechanisms.

##### 4.42.5.3.1 Sulfide stress corrosion cracking (SSCC)

When atomic hydrogen diffuses into a steel matrix, it embrittles the material, reducing the ductility and the toughness of the material. Embrittled steel is less tolerant to defects and can readily crack, either under the action of an applied tensile stress (e.g., due to the internal pressure in the pipeline) or as a result of residual stresses in the pipe wall (e.g., as a result of welding). In a sour environment, this cracking is called SSCC. Weld areas are particularly susceptible to SSCC, as the welding can produce hard zones that embrittle more easily in a hydrogen environment.

Under test conditions, SSCC has been shown to cause failure within hours of exposure to the sour environment and therefore it is imperative that materials used in the pipeline construction have been selected appropriately and that welding procedures are designed to limit the hardness in the HAZ. Although postweld heat treatment may be applied to reduce the residual stress and temper any hard microstructures in the steel, this is not feasible for pipelines.

##### 4.42.5.3.2 Hydrogen-induced cracking (HIC)

Although there are differing theories in the literature, one mechanism for the formation of HIC is that atomic hydrogen diffuses into the steel and collects around nonmetallic inclusions, particularly sulfide laminations in the pipe wall. At these locations, the hydrogen atoms can recombine to form hydrogen gas. As hydrogen gas is unable to diffuse in steel, the hydrogen gas pressure in the internal voids builds up to such a high level that the steel can crack. This process is represented in [Figure 10](#). The cracks propagate away from the voids and the crack path is influenced by microstructure, particularly in rolled plate where the cracks run along the banded rolling microstructure, parallel to the pipe wall.

If HIC is initiated at different locations in the pipe wall, it is possible for the cracks to link up by growing at right angles to the pipe wall (i.e., in a radial direction). For this reason, HIC is sometimes referred to as stepwise cracking. In addition, if the inclusion is close to the pipe wall, the pressure of the hydrogen gas may be sufficient to cause local yielding and can result in visible blistering on the pipe surface.

As with SSCC, failure by HIC can be very rapid, and under test conditions, has been found to occur within days of exposure to a wet, sour environment.

**Figure 10** Mechanism of HIC in pipeline steels.

#### 4.42.5.3.3 Stress-oriented HIC (SOHIC)

HIC is not influenced by the stress state of the pipeline. However, under the influence of either the operating stress or a residual stress, the HIC cracks can become aligned perpendicular to the principal stress direction in a characteristic array of small, staggered cracks. This type of cracking is known as Stress-oriented HIC (SOHIC).

#### 4.42.5.4 Material Selection for Sour Service

High-strength steels are more susceptible to hydrogen embrittlement and therefore cracking in a sour environment and consequently steels have to be selected to comply with maximum hardness levels to avoid cracking in both the parent and the weld material. The risk of sour service cracking such as HIC is also reduced by producing steels with the minimum of inclusions. This is achieved by using steel with very low sulfide concentrations to avoid the formation of MnS inclusions. In addition, the surface area of the inclusions is reduced by the addition of Rare Earth Metals (REMs) and calcium, which form spherical inclusions rather than elongated inclusions and therefore there is less inclusion area on which hydrogen can accumulate. Suitable pipeline materials for use in sour service are specified in the International Standard NACE MR0175/ISO15156-2:2003.<sup>32</sup>

#### 4.42.5.5 Microbiologically Induced Corrosion

The final type of internal pipeline corrosion to be considered here is MIC. This type of corrosion was described earlier with respect to microbe activity in soil resulting in external MIC (Section 4.42.4.1.2). However, SRBs can also be present in the reservoir and can be carried over into the pipeline if the system is not properly treated with an appropriate biocide.

SRBs can cause MIC and can also increase the H<sub>2</sub>S content in the product. SRBs that appear in reservoirs over time are usually due to the contamination of the reservoir during completion or water injection.

#### 4.42.5.6 Internal Corrosion: Prevention

In the control of external corrosion, the principle of protection is based on the combination of a pipeline coating, to prevent the electrolyte from contacting the pipe wall and to restrict the flow of the corrosion current, and CP, to make the pipeline the cathode in the corrosion cell. The rationale for corrosion protection of pipelines from internal corrosion is principally to accept that corrosion is going to occur if water cannot be removed from the system but to take steps to reduce the corrosion rate or to allow for corrosion within the pipeline design. The latter step is provided by the use of a corrosion allowance or by using more corrosion-resistant alloys and the former could include such measures as product treatment, inhibition, and internal coating. These strategies are discussed in more detail in the following sections.

##### 4.42.5.6.1 Corrosion allowance

A corrosion allowance is additional material that is added to the pipe wall thickness to allow for predictable, in-service corrosion. The corrosion allowance in pipeline design is calculated by predicting the corrosion rate in the pipeline, taking into account the anticipated effectiveness of other corrosion control strategies, and allowing for that amount of controlled, uniform wastage of the pipe wall over the design life of the pipeline. In practice, typical corrosion allowances for carbon steel are between 3 and 5 mm.<sup>33</sup> However, in situations where the corrosion rate is predicted to be high, the use of a corrosion allowance may not be viable due to the cost of the extra material required.

Strictly speaking, providing a corrosion allowance is not a corrosion prevention method as corrosion is still assumed to continue, but it can increase the design life of a pipeline that is susceptible to internal corrosion.

#### 4.42.5.6.2 Corrosion-resistant alloys

For pipelines that are transporting unprocessed product over short distances, the use of a corrosion-resistant alloy may be feasible. Chromium is the most commonly used alloying element for steel to improve the corrosion resistance in wet CO<sub>2</sub> environments. Even at low levels (0.5 – 1%Cr), there have been reports of improvements in corrosion resistance, an observation that is thought to be due to the fact that Cr acts to stabilize the iron carbonate film. Higher additions of Cr and Ni, as in stainless steels, can make the steel resistant to CO<sub>2</sub> corrosion and the improved corrosion resistance in these cases is due to the formation of a chromium oxide scale on the surface. However, as with all surface scales, if the scale becomes damaged and is not reformed, the pipeline becomes susceptible to pitting corrosion. For stainless steels, the presence of high levels of chloride can result in pitting corrosion.

Although the use of more corrosion-resistant alloys may be viable for short lengths of pipeline, for transmission pipelines, it is not an economical solution to internal corrosion, and carbon steel is the construction material that is used. However, for transmission pipelines, there is the opportunity to process the fluid and to add chemical inhibitors to reduce the corrosion rate.

#### 4.42.5.6.3 Coatings

Internal coatings are used particularly in gas pipelines to improve pipeline flow efficiency by reducing frictional losses. However, it is also possible to use internal coatings to protect the pipeline if it is going to be transporting a highly corrosive product. Either the coating can be applied in the mill with the girth welds coated after construction or the entire pipeline can be coated *in situ* by introducing the coating medium between cleaning tools after the pipeline has been constructed.

It is recalled that for external corrosion protection, both pipeline coating and CP are applied to control corrosion, as it is impossible to maintain a coating in a defect-free condition. The problem with relying on a coating to provide internal corrosion protection is that, where the coating becomes damaged, corrosion could occur very rapidly and therefore these areas of

damage have to be protected. Coatings should therefore be used in conjunction with inhibitors to reduce the corrosion rate at the sites of damaged coating.

#### 4.42.5.6.4 Product treatment

Based on the descriptions of both sweet and sour corrosion, it can be stated that pipeline internal corrosion will not occur if water is not present. Therefore, one of the key corrosion prevention strategies is to remove water from the product prior to pipeline transportation. The decision to use dehydration obviously carries a cost penalty and provision must also be made for upsets in the water separation and dehydration systems to prevent significant internal corrosion under these conditions.

Another treatment that can be applied to the product is pH control. It was mentioned in [Section 4.42.5.1.3](#) that the corrosion rate decreases as the pH increases, and therefore, the addition of alkaline additives to raise the pH can be used to control corrosion.

Large quantities of glycol or methanol are often introduced into wet gas-producing systems to prevent and control hydrate formation, which can cause plugging problems. Both of these chemicals, if present in sufficient concentrations, can also reduce CO<sub>2</sub> corrosion rates.

#### 4.42.5.6.5 Inhibitors

Inhibitors are principally used for the control of general corrosion in sweet environments. However, there are packages available for the control of mesa type corrosion and pitting corrosion in both sweet and sour environments. The selection of an inhibitor to adequately protect a pipeline requires consideration of a number of interrelated factors. Detailed information on the use of inhibitors can be found in texts such as the European Federation of Corrosion publication.<sup>33</sup> However, the key factors and considerations with respect to pipelines are discussed in the following sections.

Corrosion inhibitors used in hydrocarbon pipelines are generally long-chain nitrogen-based compounds (e.g., amines, amides), but they can also be organophosphates. These compounds have a charged surface-active group and a hydrocarbon chain. The surface-active groups are attracted to the pipe wall where they become physically adsorbed and then chemisorbed onto the surface as charge transfer with the pipe wall occurs and a chemical bond is formed. In oil pipelines, the hydrocarbon chains in the inhibitor molecules mean that the inhibitor becomes partially oil soluble and therefore forms a

hydrophobic barrier between the steel and the water phase. The principle of inhibition is therefore two-fold: the removal of water from the pipe surface through the formation of a stable film and the modification of the surface potential, inhibiting both the anodic and cathodic reactions. In addition to the active species, the inhibitor will also include a solvent carrier fluid and other additives, such as surfactants to optimize the delivery and storage properties of the inhibitor.

It is highlighted that inhibitors do not stop corrosion but the aim of inhibition is to reduce the corrosion rates to manageable levels. The effectiveness of the inhibitor regime is measured by the efficiency, which is defined as:

%Inhibitor Efficiency

$$= \left[ 1.00 - \frac{\text{Weight loss (with inhibitor)}}{\text{Weight loss (without inhibitor)}} \right] \times 100$$

Although laboratory tests have shown that efficiencies of more than 95% can be achieved, in practice, most operators achieve an inhibitor efficiency of 80–90%,<sup>33</sup> although higher efficiencies may be expected if the inhibitor has been carefully selected.

In order for an inhibitor to be effective, it must be dispersed to those surfaces that are wet by water and must be able to establish and maintain a protective film at that location. The transport of the inhibitor to all corroding sections along the full length of the pipeline is therefore important, whether the corrosion is at the bottom of the pipeline due to water drop out or at the top of the pipeline due to condensation (Section 4.42.5.1), at the start of the line or toward the end of the line. There are two main methods for introducing inhibitor into the pipeline: continuous injection and batching.

In continuous injection, the inhibitor is dispersed by the flowing product. For gas pipelines, this requires the inhibitor to be injected either as a separate liquid phase or as droplets entrained within the gas phase. However, the distance of travel of the inhibitor is limited using this method and therefore inhibition is not really a viable corrosion control option for gas pipelines. Continuous injection is more generally used for multiphase pipelines or pipelines containing crude oil and condensate where the transport of the inhibitor is in the liquid phase. In this situation, the inhibitor type has to be specified depending on the particular conditions and whether the inhibitor is required to be soluble in the oil or water phases in the carrier fluid.

In batch treatment, the inhibitor is introduced into the pipeline as a slug between two cleaning tools and is used in situations where continuous injection may not be an option or where TOL corrosion is expected and the flow regime does not allow the transport of inhibitor to this location by continuous injection. The frequency of batching is dependent on the inhibitor and the flow conditions in the pipeline.

Another important factor that has to be considered in the specification of an inhibitor is the dosing rate. The dose rate has to be monitored continuously to ensure that sufficient inhibitor is being injected to account for changes in water concentration in the pipeline. The dose rate is also dependent on how the inhibitor partitions between the oil and water phases. The aim is to obtain a sufficient concentration of the inhibitor in the water phase at the location of the corrosion and it is this concentration that must remain constant through the adjustment of the amount of inhibitor injected into the pipeline.

The performance and effectiveness of an inhibitor is also dependent on other factors such as the flow rate (turbulent flow can prevent the inhibitor film from forming or can strip the film from the pipe wall), temperature, composition of the product, interaction with other chemical additions, and pressure. These factors can change throughout the life of the pipeline and particularly during upset conditions, and therefore, it is important that continuous monitoring is employed to ensure that adequate inhibition is being achieved.

#### 4.42.5.7 Internal Corrosion Monitoring

Internal corrosion monitoring can either be used to determine the effectiveness of the corrosion prevention strategies and to detect any upset conditions that could increase the corrosion rate in the pipeline, or to take measurements of corrosion rate. In practice, it is recommended that more than one technique is used and that monitoring is not reliant on only one type of measurement.

The types of monitoring used to determine whether corrosion prevention is being achieved include measurements of water content and chemistry, inhibitor availability, inhibitor dose rate, and inhibitor residuals (i.e., estimates of the concentration of inhibitor in the water phase). However, while these techniques may indicate that the pipeline is corroding, they will give no information on the rate of corrosion or location of that corrosion. Iron counts (i.e., measurements of the amount of iron entering the water phase as a result of

corrosion) can also be used to indicate the effectiveness of the inhibitor program but it is not possible to determine whether the increased iron content is as a result of localized pitting or general corrosion, and therefore, calculating realistic corrosion rates using this method is difficult.

There are therefore alternative monitoring techniques that can be used to provide an indication of corrosion rate. These include weight loss corrosion coupons and probes that are inserted into the pipeline through hot tap fittings or through valves and access points. Immediately, this highlights one of the limitations of this type of monitoring: a measurement is only available at the location of the probe and this location is often selected due to ease of access rather than corrosion risk. The selection of appropriate locations for monitoring equipment should be made through evaluation of the pipeline operation and route and considering such factors as low points, flow regimes, temperature, and potential localized corrosion effects.

Coupons are the oldest method of monitoring corrosion. They are strip or disk-shaped coupons manufactured from the same steel as the pipe wall. The coupon is weighed and inserted into the process stream. At regular intervals, the coupon is then removed and weighed to determine the amount of weight loss since the last measurement, which will determine the average corrosion rate over that time period. The coupon can also provide useful information regarding deposits,

fouling, and localized corrosion that may be occurring in the pipeline.

There are several types of insert probes that are available, that are based on measurements of changing ER probes or linear polarization resistance measurements (LPR probes). ER probes can provide a measurement of the average corrosion resistance, whereas LPR probes have the advantage of providing instantaneous data. The disadvantage of LPR probes is that they need to be immersed in a conductive medium, which in practice means the water phase.

Other monitoring techniques that can be used include specially instrumented pipeline spools and ultrasonic mats. However, with these techniques, it is critical that the equipment is placed in the locations at highest risk of internal corrosion to ensure that relevant readings are taken.

#### 4.42.5.8 Assessing the Internal Corrosion Risk

The preceding sections have identified the types of data that are required to assess the risk of sweet and sour internal corrosion in pipelines, both from the point of view of the factors that contribute to the threat and also in respect of the prevention and monitoring activities that are conducted by the pipeline operator. A summary table of the type of data required is presented in [Table 9](#). As with the external

**Table 9** Summary of typical information required to assess the internal corrosion threat

	<i>Data required to assess threat</i>	<i>Comment</i>
<i>Pipeline characteristics</i>	Pipe and weld material	Could highlight a susceptibility to certain forms of corrosion (e.g., preferential weld corrosion) and is also required to determine suitability for sour service.
	Pipeline type	For example, whether the pipeline is a gathering or transmission line could indicate how much preprocessing has been conducted on the product.
<i>Pipeline operation</i>	Flow regime	Indicates the susceptibility to mesa or FILC corrosion.
	Upset conditions	Indicates how likely water is to enter into the pipeline.
<i>Product data</i>	Product analysis	Indicates susceptibility to sweet or sour corrosion and likely corrosion rates. Could include such information as water content, pH, CO <sub>2</sub> partial pressure, H <sub>2</sub> S partial pressure, O <sub>2</sub> content.
	Temperature	With product analysis data, indicates typical corrosion rate and also the likelihood of scale formation and therefore susceptibility to certain types of corrosion.
	Inhibitor efficiency Inhibitor availability	Indicates whether the inhibitor is likely to have been adequately protecting the pipeline and therefore the period over which corrosion could occur.
<i>Monitoring information</i>	Coupon and probe data	Provides information on the likely corrosion rates in the pipeline.
	Leak history Previous inspection reports	Provides more quantitative evidence of a corrosion threat.

corrosion threat, this information can be used in semiquantitative risk assessment algorithms to determine how susceptible a pipeline may be to internal corrosion.

#### 4.42.6 External SCC Risks

Although pipeline failures due to external SCC are relatively rare, it is worth including a brief description of this threat in a discussion of pipeline corrosion. OPS statistics indicate that only 1% of reported incidents in North American transmission and gathering pipelines (natural gas and hazardous liquids) between 1985 and 1996<sup>34,35</sup> have resulted from SCC. However, for specific pipelines, SCC can be the dominant failure mechanism and the consequences can be extremely serious. Although many of the reportable incidents of SCC have occurred in gas pipelines, failures have also been reported on liquid pipelines<sup>36</sup> and almost all cases of SCC have been encountered in pipe installed for more than 10 years with no failures reported to date for pipe that is less than 5 years old.

Two forms of external SCC have been identified on high-pressure gas transmission pipelines; high-pH SCC and near-neutral pH SCC. High-pH SCC was responsible for the first recognized failure due to SCC, in Louisiana in 1965, and incidents of this form of cracking have since been reported in Australia, Iran, Iraq, Italy, Pakistan, and Saudi Arabia. Near-neutral pH SCC was first identified in 1985 and has typically been associated with incidents in northern climates such as northern United States, Canada, and Russia.

For either form of SCC to occur in a pipeline, a complex array of conditions must be met including a critical combination of operating stress and stress cycling, faults in both the protective coating and the applied CP, a susceptible steel, and moisture at the pipe surface.

##### 4.42.6.1 Nature and Occurrence of SCC

SCC is a corrosion process in which the form or geometry of the corrosion is strongly influenced by stress. As a result, the corrosion process creates linear, crack-like defects rather than rounded corrosion pits or general metal wastage. The stress corrosion cracks grow at right angles to the principal stress, and hence, on an operational pipeline, where the principal stress is generated by internal pressure, it is most usual for the cracks to be aligned parallel to the axis of the pipeline. However, a number of instances of circumferential SCC have also occurred where high axial

stresses have been developed due to geotechnical instabilities.<sup>37</sup>

##### 4.42.6.1.1 High-pH SCC

High-pH SCC is the most common mode of SCC and is characterized by intergranular cracking, following the grain boundaries within the steel microstructure. Weak points or areas of damage of the protective magnetite iron oxide film ( $\text{Fe}_3\text{O}_4$ ) that forms on the steel surface, particularly at grain boundaries, are preferential sites for corrosion and crack-like features are formed at these locations. One theory for the mechanism of grain boundary cracking is that the grain boundaries act as stress raisers causing the oxide film to crack at these locations under the influence of a cyclic stress. In the alkaline environment of high-pH SCC, active dissolution will then occur at grain boundaries where the steel may also be less corrosion resistant due to grain boundary segregation. The water in the region of the crack is generally found to be alkaline with a pH above 10.

In order for SCC to occur, three conditions must be satisfied concurrently: there must be a tensile stress, a cracking environment, and a material that is susceptible to cracking in that environment. The factors that affect these conditions are discussed under these three headings:

- *Effect of stress*

It is generally accepted that there is a threshold stress, below which stress corrosion cracks will not occur. In the absence of a sustained cyclic stress, the threshold stress approaches yield. However, incidents of high-pH SCC in the US have generally been observed in pipelines where the combined stress level (i.e., from internal pressure and secondary loading) is above 60% of the minimum yield stress of the material.

An alternating stress on the pipeline has two effects in contributing to high-pH SCC failure: first, it reduces the threshold stress for crack initiation, and second, it damages the protective oxide film, preventing it from reforming and allowing the SCC to propagate.

- *Effect of environment*

High-pH SCC is generally found in areas where the CP is working and occurs in otherwise unaffected pipe with little or no associated corrosion. This is principally due to the formation of the magnetite film under the high pH conditions. However, there is a critical potential for high-pH SCC cracking, which is dependent both on the temperature and on the pH level. Typically, cracking occurs at potentials

$\sim -750$  mV with respect to a standard copper/copper sulfate electrode and the range over which cracking will occur is  $\sim 100$  mV. This means that the critical potentials are less negative than the generally accepted requirement of  $-850$  mV for effective CP of a pipeline (see [Section 4.42.4.2.12](#)). It is therefore important that the CP protection criteria selected do not allow the potential to drop into the cracking region. It was highlighted in [Section 4.42.4.2.12](#) that this is of particular concern if the 100 mV shift criterion is used. In addition, the coating should be well maintained to prevent areas of disbonding, which could partially shield the pipe and lower the potential.

Although there has been no reported correlation between soil chemistry and the occurrence of high-pH SCC, it has been observed that pipelines that are located in soils that are alternately wet and dry are more susceptible. Areas that are continually wet, such as in rivers or lakes, have not experienced SCC to the same extent as has occurred on the edges of streams or lakes.

Temperature has an effect on the growth rate of high-pH SCC and also influences the range of potentials over which cracking will occur. There is also an observed relationship between the occurrence of high-pH SCC and the distance from a compressor station. Most severe cracking is generally found within  $\sim 5$  km of compressor outlets and falls to a low level at  $\sim 16$  km. Although there are other factors that could contribute to this observation, such as alternating stresses, one of the contributors could be temperature as the temperature of the product is raised as it passes through the compressor station.

Although the pipe coating does not have a direct influence on high-pH SCC initiation and growth, the coating properties do influence the formation of an environment and a potential conducive to cracking. High-pH SCC will only occur in pipelines where the coating has failed in some manner. The likelihood of coating failure and disbondment is increased at higher temperatures, which could also be a contributing factor to the observed increase in cracking incidences close to compressor stations. It is highlighted that no SCC has been found to date under undamaged FBE coatings.<sup>38</sup> However, further experience with the use of FBE may be required before it can be concluded that this coating provides resistance to SCC.

- *Effect of material*

There is no apparent correlation between pipe grade or manufacturing process and the risk of high-pH SCC. However, grit blasting of the surface to remove

surface scale has been shown to avoid or delay the onset of cracking. Firstly, this relates to the cracking potential; if the steel is clean, then it is difficult to maintain the potential in the cracking range. Secondly, if the surface is grit blasted, then the coating will also adhere more easily, and finally, grit blasting will leave the surface in a state of compression and therefore more resistant to crack initiation.

#### 4.42.6.1.2 Near-neutral pH SCC

Near-neutral pH SCC is characterized by a transgranular mode of cracking, where the cracks grow through the grain structure without following boundaries. These cracks also initiate at the pipe wall and form in clusters, often more closely spaced than is the case for high-pH SCC. However, in contrast to the tight nature of high-pH SCC, near-neutral cracking tends to be wider and more open and is often filled with corrosion product. The water surrounding the crack appears to be neutral with a pH  $\sim 7$ . The mechanism of near-neutral pH SCC is still a subject of research but is thought to involve both the dissolution of oxide films and hydrogen embrittlement. Near-neutral pH SCC is often associated with general pitting or metal loss and the cracks can sometimes be embedded within corrosion pits, which can make detection difficult. It is also often, but not always, associated with welds.

As with high-pH SCC, the cracking requires a combination of stress, environment, and material.

- *Effect of stress*

Near-neutral pH SCC requires a tensile stress acting on the pipeline. In addition, stress raisers and residual stresses are also thought to play a significant role in the initiation of near-neutral pH SCC. Pressure cycling has also been shown to influence both the rate of crack growth and the threshold stress for near-neutral pH.

- *Effect of environment*

Laboratory tests indicate that near-neutral SCC occurs at or near the free corrosion potential for steel. Cracking only occurs therefore in pipelines where there is inadequate CP or where the pipe is shielded from the CP, for example, by a disbonded coating.

As with high-pH SCC therefore, the role of the coating is to enable the cracking environment to be developed at the pipe surface. The majority of failures have occurred on pipelines with field-applied PE tape. The coating failure mode is thought to

influence the crack development. For example, tenting of the coating over the long seam creates a long narrow zone in which cracks can easily coalesce and link up. Disbonding of coal tar coating tends to be localized around a defect and any resulting crack cluster is shorter and broader.

The composition of the soil does not seem to be critical to this type of cracking, although the amount of carbon dioxide in solution does appear to be important. For this reason, cracking generally occurs in colder climates where the carbon dioxide levels are higher. High levels of carbon dioxide are particularly found in winter under frozen surfaces.

There does not appear to be any relationship between temperature and the initiation and growth of near-neutral SCC. Therefore, with respect to temperature, there is no equivalent correlation between the incidence of cracking and the distance from compressor station as there is with high-pH SCC. It is possible, however, that the increased stresses close to compressor stations may be a contributing factor in near-neutral SCC.

- *Effect of material*

Near-neutral pH SCC has been identified in a range of steel grades and manufacturing routes. Research has shown that important material factors that correlated with the incidence of near-neutral pH SCC were residual stress, local increases in microhardness, and increased surface roughness. However, no correlation was reported with chemical composition, inclusions, and stress strain behavior. Surface preparation prior to coating application is less critical to near-neutral pH SCC than for high-pH SCC.

#### 4.42.6.2 Assessing the SCC Risk

The preceding sections have described the critical risk factors that render a pipeline susceptible to high-pH SCC. On the basis of these criteria, ASME B31.8S<sup>18</sup> Appendix A3.3 has defined the areas of a pipeline at greatest risk as

- the pipeline operating stress is greater than 60% of the minimum yield stress of the steel;
- the operating temperature is greater than 37 °C;
- the distance from a compressor station is <32 km;
- the pipeline is older than 10 years; and
- the pipeline coating is not FBE.

These criteria have also been adopted by the NACE Recommended Practice NACE RP0204<sup>38</sup> to identify

areas of greatest risk from near-neutral pH SCC, although the temperature criterion has been removed. In addition, if there has been one or more service incidents or hydrotest leaks that were attributable to SCC, then a SCC integrity management plan has to be put in place.

#### 4.42.7 Corrosion Inspection Techniques

In [Section 4.42.3](#), the concept of using risk assessment procedures to identify the critical pipeline threats was introduced. The following sections then detailed the principal internal and external corrosion mechanisms that can be present on onshore pipelines and detailed some of the risk factors that are used in risk assessments.

Once the risk of a particular corrosion mechanism or threat has been highlighted, the next stage in the process ([Figure 3](#)) is to inspect the pipeline to confirm or otherwise the existence of the threat, locate the damage and, if possible, identify the extent of the damage. The type of inspection method that is used is dependent on the type of corrosion or cracking and the accessibility of the pipeline for that inspection technique.

Three inspection methods that can be used for the inspection of corrosion-related threats in onshore pipelines are discussed in the following sections. It is highlighted that more than one inspection technique may be required to identify all the corrosion threats on a pipeline and when a particular inspection method has identified the location of damage, further nondestructive evaluation may be required to fully categorize the damage.

##### 4.42.7.1 In-Line Inspection

In-line inspection (ILI) is an inspection method that can locate and size defects on a pipeline, not only corrosion defects but also defects arising from manufacturing, construction, and mechanical damage. There are two basic technologies that are used for the detection of corrosion on pipelines using ILI tools: magnetic flux leakage (MFL) and ultrasonics (UT). The ILI tools are inserted into the pipeline through specially designed traps and the majority are free-swimming tools that are propelled by the flow of the product in the pipeline. This is one of the advantages of ILI over some other inspection methods in that the product flow does not have to be interrupted to conduct the assessment.

#### 4.42.7.1.1 MFL for corrosion

MFL tools detect defects by the application of a magnetic field in either the longitudinal or circumferential direction. As the tool travels through the pipeline, powerful permanent magnets magnetize the surrounding metal via wire brushes that contact the pipe wall. Sensors surrounding the circumference of the tool record the change in the magnetic field. This change in magnetic field can then be related to metal loss defect dimensions, using algorithms developed from test runs in pipes with machined defects of known dimensions. It is important to note therefore that the tools using MFL technology do not make direct measurements of remaining wall thickness.

As already mentioned, the magnetic field can be orientated either in the axial direction, to detect corrosion with a larger circumferential aspect ratio, or in the circumferential direction, to detect corrosion with more of a longitudinal extent. Examples of longitudinal corrosion would include internal sweet corrosion caused by water drop out or external axially extended corrosion caused by loss of coating adhesion around the longitudinal seam weld.

MFL tools can be used to inspect both liquid and gas pipelines and can discriminate between internal and external corrosion. The accuracy of sizing of the defects is dependent on the geometry of the features and the resolution of the tool.

#### 4.42.7.1.2 Ultrasonic wall thickness measurement (USWM)

USWM tools are based on a system that uses the ultrasound echo time technique to measure the remaining wall thickness of pipes by sending an ultrasonic beam at  $90^\circ$  through the pipe wall. The inspection tool has a number of ultrasonic sensors mounted in a carrier and orientated such that they provide maximum coverage of the pipe wall. The sensors act as both transmitters and receivers of the ultrasound. Once the ultrasound leaves the sensor, it is reflected from both the inner and outer surfaces of the pipe wall (Figure 11). If there is a defect in the pipeline, then the ultrasound will be reflected from the defect and the time between the sound leaving and returning to the sensor is a direct measurement of the remaining wall thickness at that location. The difference in the stand-off distance (i.e., the distance between the sensor and the pipe wall) at the location of the defect indicates whether the corrosion is internal or external. USWM can also detect HIC cracking in pipelines where the HIC is running parallel to

Figure 11 Principle of operation of USWM.

the pipe wall. For example, in the illustration in Figure 10, ultrasound traveling at  $90^\circ$  to the pipe wall will be reflected by the HIC.

One of the main limitations of ultrasonic inspection tools is that they can only be used in liquid pipelines as a liquid couplant is required between the sensor and the pipe wall to allow the ultrasound to travel into the pipe wall. If ultrasonic ILI is to be conducted in a gas pipeline, then the tool must be run in a liquid slug.

#### 4.42.7.1.3 ILI for crack detection

Although the ILI tools described earlier can detect metal loss features and a limited amount of cracking, in order to identify SCC and certain types of sour cracking, a separate crack detection inspection must be undertaken.

For liquid pipelines, ultrasonic crack detection (USCD) is the most appropriate tool. The principle of the inspection is similar to USWM except that the pulses of ultrasound emitted by the tool are directed circumferentially into the pipe wall at an angle that generates  $45^\circ$  shear-waves within the metal. The angle of incidence means that the beam is reflected and diffracted from axially aligned cracking.

For gas pipelines, using the USCD tool would require the inspection tool to be run in a liquid slug. Therefore, the most appropriate inspection tool for gas pipelines uses electromagnetic acoustic technology (EMAT). EMAT allows ultrasound to be generated in a steel pipe wall without the requirement for a liquid couplant to transfer the ultrasound into the steel. A magnetic field is established in the pipe wall using magnets. A coil carrying AC current at  $90^\circ$  to the magnetic field produces eddy currents in the pipe wall. A force normal to the pipe wall is exerted on the eddy currents, which generates ultrasound traveling through the pipe wall.

#### 4.42.7.1.4 Benefits of in-line inspection

The main benefit of ILI is that no interruption to the flow of product is required to inspect the pipeline and it is possible to obtain data for the entire length of the pipeline. Besides providing information on the defect sizes, an ILI inspection will also allow patterns of corrosion activity to be identified that assist in the diagnosis of the corrosion problem. For example, a clustering of external corrosion features around girth welds could highlight a problem with the girth weld coating. If this information was combined with above-ground survey data that indicated that there were no defects in the coating and that the CP was adequately protecting the pipeline, then this pattern could further indicate that there was a potential disbonding problem with the coating. Another benefit of ILI is that corrosion growth studies can be conducted using the data from two inspection runs and comparing the sizes of defects between the two data sets. This type of analysis allows corrosion rates to be calculated for internal and external corrosion features at different locations along the pipeline.

#### 4.42.7.2 Hydrotesting

It is a requirement of commissioning that all pipelines undergo a hydrotest at a pressure above the maximum allowable operating pressure prior to entering service. The major aim of the pressure test is to prove the integrity of the pipeline by deliberately testing to a pressure higher than the operating pressure. As a result, all defects large enough to cause failure during service are removed. The test pressure and the duration of the test are specified in pipeline design codes and are dependent on the product and the location of the pipeline. It is also possible to conduct a hydrotest during the operating life of the pipeline with the same aim, to remove defects that would fail at the operating pressure.

There are several factors that have to be considered before selecting a hydrotest as the optimum method for assessing the integrity of the pipeline. Firstly, the pipeline has to be taken out of service and filled with water, which can be a time-consuming and costly process. If not properly removed, the hydrotest water can also cause internal corrosion and therefore it is imperative that the pipeline is properly dried following the test. Another drawback of this test is that the criterion for determining whether the pipeline is safe is pipeline failure. For buried onshore pipelines, locating the leaking defect and repairing it is not an inexpensive or trivial task. Finally,

the hydrotest will only identify those defects that were unacceptable on the day of the test. For time-dependent defects, such as corrosion or SCC, the test interval has to be selected such that defects that pass the test will not grow to an unacceptable size prior to the next test.

#### 4.42.7.3 Direct Assessment

Direct assessment is defined in ASME B31.8S<sup>18</sup> as “an integrity assessment method utilizing a structured process through which the operator is able to integrate knowledge of the physical characteristics and operating history of a pipeline system or segment with the results of inspection, examination, and evaluation in order to determine the integrity.” Currently, this standard allows direct assessment methods to be used to assess the pipeline integrity with respect to external corrosion (ECDA), internal corrosion (ICDA), or stress corrosion cracking (SCCDA).

In practice, direct assessment involves remotely identifying or predicting the locations along the pipeline where the risk of damage from a particular threat is high. Depending on the threat, this identification can utilize techniques such as above-ground corrosion monitoring (see [Sections 4.42.4.2.5 and 4.42.4.2.15](#)), hydraulic analysis, predictive models, and operator experience. Direct field measurements are then made at the high-risk locations by excavating the pipeline at these sites and using standard non-destructive inspection techniques such as visual examination, magnetic particle flaw detection, and ultrasonic inspection to size and assess the damage. These results are then fed back into the assessment procedure to determine whether further sites require excavation, to assess the integrity of the pipeline and to set the reinspection interval for the next direct assessment.

If an operator is to apply the direct assessment process, he/she has to develop a direct assessment plan, the requirements of which are dependent on the threat being addressed. Obviously, the highest resolution direct assessment that can be achieved is to excavate an entire pipeline segment and apply direct examination techniques, but this would also be extremely costly and in some cases impractical. However, direct assessment approaches do allow the pipeline operator to draw conclusions regarding the integrity of the pipeline from a limited number of excavations and supporting data (e.g., above-ground survey data, predictive models) for the remainder of the pipeline that is not excavated.

Direct assessment principally finds application for both liquid and gas pipelines that are uninspectable by ILI or where the supply of product cannot be interrupted to conduct a hydrotest or to allow pipeline modification for internal inspection.

#### **4.42.7.3.1 External corrosion direct assessment (ECDA)**

The objective of direct assessment for external corrosion is to locate areas along the pipeline where the coating has become damaged and the CP system is not effective, that is, areas where active external corrosion could be occurring. The process is conducted in four stages: preassessment, indirect examination, direct examination, and postassessment.

The first stage is essentially confirming that ECDA is feasible for the pipeline and selecting appropriate above-ground methods for locating areas of corrosion damage. For example, it was described in [Section 4.42.4.2.13](#) how above-ground methods cannot be used in locations where disbanded coatings result in electrical shielding of the pipeline. In these locations, alternative methods of pipeline assessment must be used and these must be defined in the preassessment stage. In the indirect examination, the pipeline is inspected at least twice using two above-ground survey techniques, for example, a CIPS survey can be used to locate regions of underprotection in the CP and a DCVG survey could locate regions of coating damage. The reason that two complementary techniques are used is to ensure that the strengths of one tool compensate for the limitations of another. The results of these two surveys are then aligned to identify regions where the CP and/or the coating are failing. These areas would then be classified and the most severe areas would be subjected to direct examination by exposing the pipeline.

During the direct examination stage, measurements are taken of the pipeline environment and CP, the coating, the corrosion dimensions, and the extent of cracking (if any). These measurements allow assessments to be made regarding the corrosion cause, the fitness-for-purpose of the defect, and the corrosion rate. One of the key requirements of this stage is to validate the classification that has been given on the basis of the indirect examination (i.e., minor, moderate or severe). The number of digs required by the standard is dependent on the results of the direct examinations relative to the initial classification. Finally the postassessment stage defines the reassessment intervals and assesses the overall

effectiveness of the ECDA process, particularly with respect to the predictions made in the preassessment stage.

#### **4.42.7.3.2 Internal corrosion direct assessment (ICDA)**

Similar to ECDA, the purpose of ICDA is to identify areas where internal corrosion is occurring or has occurred along a pipeline. Currently, the procedure as defined in ASME B31.8S<sup>18</sup> is only applicable to gas pipelines that normally operate dry but may suffer from an upset that allows water to enter the pipeline. The principle of ICDA is based on the assumption that water will first settle at the low points in the pipeline or at locations where the angle of inclination is exceeded for specific gas flow velocities. If examinations are made at these points and no corrosion is detected, then it can be assumed that the remaining lengths of the pipeline will not be corroded.

As with ECDA, there is a preassessment that determines whether the method is appropriate for the pipeline. The identification of the direct examination sites is achieved by conducting flow calculations taking into account information on the route topography of the pipeline. At points where internal corrosion could occur, ultrasonic measurements are taken on the excavated pipe to determine the remaining wall thickness. The requirement for conducting further examinations is based on the results of the direct examinations.

#### **4.42.7.3.3 Stress corrosion cracking direct assessment (SCCDA)**

The procedure for conducting SCCDA is outlined in the NACE document RP0204<sup>38</sup> and follows a similar methodology to that previously described for ECDA, that is, preassessment, indirect examination, direct examination, and postassessment.

The preassessment stage of the SCCDA procedure determines whether the whole pipeline or a section of a pipeline is susceptible to SCC using the factors described in [Section 4.42.6.2](#) for high-pH SCC and removing the temperature criterion for the assessment of near-neutral pH SCC. NACE RP0204<sup>38</sup> also contains guidance regarding more detailed information that could be collected about the pipe material, the construction of the pipeline, the environment, corrosion control, and operation of the pipeline that could indicate an increased susceptibility to SCC. If a section of a pipeline is found to be susceptible, then further investigation has to be made, by hydrotesting, ILI, or by direct assessment.

In this respect, SCCDA may act as complimentary methodology to ILI or hydrotesting rather than as a replacement for these techniques. The indirect examination step involves many of the techniques used in ECDA such as CIPS and DCVG as well as additional surveys (e.g., soil characterization) to provide supplementary information and to identify sites for direct examination.

Direct examination not only allows the relevant data to be collected to assess the SCC threat but also provides an opportunity for the external and internal corrosion threats to be investigated at the same time. It is therefore good practice, not only to conduct nondestructive examination to determine the size, type, and extent of cracking, but also to collect data on, for example, the coating condition, the nature of deposits on the pipe surface, the presence of microbes, the remaining wall thickness, etc., which will also inform the evaluation of the internal and external corrosion threat. The information collected during the direct examination stage is used to assess the integrity of the pipeline at the excavated sites and also to determine whether further sites require excavation, or whether an alternative inspection methodology, such as ILI, may be more appropriate. As with ECDA, the final step is a postassessment stage where the success of the process is reviewed and appropriate reinspection intervals are set.

#### 4.42.8 Pipeline Corrosion Management: Overview

Returning to the pipeline integrity management process introduced in Figure 3, the focus of this chapter has principally been on Steps 1 and 2 in this process, the threat identification and inspection processes. This has included a description of the factors that contribute to the threats of external and internal corrosion and SCC on land-based transmission and gathering pipelines and the appropriate inspection techniques to locate and size these defects. However, reference to Figure 3 indicates that this is only part of the continuing process of pipeline integrity management.

Once corrosion or cracking defects have been located and sized on a pipeline, whether by an in-line inspection or by direct assessment technique, the defects need to be assessed to determine whether they pose a threat to the continued operation of the pipeline under the operating stresses. The factors that control how and when a pipeline failure will occur due to corrosion are the size, shape and orientation of the

corrosion, the applied stress, and the properties of the pipe material (strength and toughness). Corrosion and crack assessment techniques for pipelines are included in codes such as ASME B31.G<sup>39</sup> modified ASME B31.G and RSTRENG<sup>40</sup> and DNV-RP-F101,<sup>41</sup> BS7910,<sup>42</sup> and API 579.<sup>43</sup> As with all assessment methods, care must be taken to ensure that the method being used is appropriate and within the validated limits of the data and the readers are referred to the code document for specific application.

If the defect is assessed as being unacceptable for continued operation, then either the pressure in the pipeline can be reduced to attain a stress level in the pipe where the defect is acceptable or the defect can be repaired. There are a number of permanent pipeline repair solutions available in the market that can be applied while the pipeline is still operational. However, in severe situations, the pipeline operator may choose to replace the section of pipe containing the defect. Obviously this is one of the most expensive pipeline repair options.

The next stage in the management cycle of Figure 3 is prevention and mitigation. This is an extremely important step in the control of corrosion and requires the corrosion engineer to be able to accurately diagnose the type of corrosion that is occurring in order that the correct mitigation actions can be implemented. Inspection data, particularly from ILI tools, can play a very important role in this diagnosis as the location and pattern of corrosion will indicate the likely mechanism of corrosion damage.

Once all the data from the risk assessment, inspection, assessment, and analysis has been collected and recorded, the cycle begins again. This illustrates the final critical point regarding pipeline corrosion management; it is not a once-for-all activity. In order to ensure that pipelines remain protected from the threat of corrosion and continue to be one of the safest modes of transport for hazardous liquid and gas products, corrosion management must be conducted on a regular and ongoing basis.

Trimethylammonium ion	9.800	541.4	−12.611	−0.015525

Note. All values are with reference to the molarity scale. Data for bases are expressed as acidic ionization constants, e.g. for ammonia we quote  $pK$  at  $25^{\circ}\text{C} = 9.245$  for the ammonium ion

The basic ionization constant of the reaction

is obtained from the relation

$$pK_a(\text{acidic}) + pK_b(\text{basie}) = pK_w(\text{water})$$

$pK_w(\text{water})$  being 13.9965 at  $25^{\circ}\text{C}$ .

**Table 21.12** Tafel constants for hydrogen evolution from aqueous solution. The Tafel equation for a cathodic reaction is  $\eta_c = a - b \log_{10} i = b \log_{10} (i_0/i)$ , where  $\eta_c$  is the overpotential (mV),  $i$  is the current density ( $\text{A cm}^{-2}$ ) and  $i_0$  is the exchange current density ( $\text{A cm}^{-2}$ )

Values of A for 20 °C for other rare gases are: Ne, 0.0101; Kr, 0.0594; Xe, 0.126. S indicates the number of m<sup>3</sup> of gas measured at 0 °C and 101.325 kN m<sup>-2</sup> which dissolve in 1 m<sup>3</sup> of water at the temperature stated, and when the pressure of the gas plus that of the water vapor is 101.325 kN m<sup>-2</sup>. A indicates the same quantity except that the gas itself is at the uniform pressure of 101.325 kN m<sup>-2</sup> when in equilibrium with water.

**Table 21.21** Oxygen dissolved in seawater (ppm) in equilibrium at 1 atm (101.325 kPa) of air saturated with water vapor*Parts per million*

Chlorinity (‰)	0	5	10	15	20
Salinity (‰)	0	9.06	18.08	27.11	36.11
<i>Temperature (°C)</i>					
0	14.62 <sup>a</sup>	13.70	12.78	11.89	11.00
5	12.79	12.02	11.24	10.49	9.74
10	11.32	10.66	10.01	9.37	8.72
15	10.16	9.67	9.02	8.46	7.92
20	9.19	8.70	8.21	7.77	7.23
25	8.39	7.93	7.48	7.04	6.57
30	7.67	7.25	6.80	6.41	5.37

Note: the table gives the quantity of oxygen dissolved in sea-water at different temperatures and chlorinities when in equilibrium with a normal atmosphere saturated with water vapor. It thus represents the condition approached by the surface water when biological activity is not excessive.

<sup>a</sup>The values of solubility in water of zero chlorinity differ slightly from those for freshwater.

**Table 21.22** Saturated solubilities of atmospheric gases in seawater at various temperatures

Gas	Chlorinity (‰)	Temperature (°C)	Concentration	
			$ml\ l^{-1}$	ppm
Oxygen	0	0	49.2 <sup>a</sup>	70.4
		12	36.8	52.5
		24	29.4	42.1
	16	0	40.1	56.0
		12	30.6	42.9
		24	24.8	34.8
	20	0	38.0	52.8
		12	29.1	40.4
		24	23.6	32.9
Nitrogen	0	0	23.0 <sup>a</sup>	28.8
		12	17.8	22.7
		24	14.6	18.3
	16	0	15.0	18.4
		12	11.6	14.2
		24	9.36	11.5
	20	0	14.2	17.3
		12	11.0	13.4
		24	8.96	10.9
Carbon dioxide <sup>b</sup>	0	0	1715 <sup>a</sup>	3370
		12	1118	2198
		24	782	1541
	16	0	1489	2860
		12	980	1888
		24	695	1342
	20	0	1438	2746
		12	947	1814
		24	677	1299

<sup>a</sup>These values differ slightly from those for freshwater.<sup>b</sup>Includes CO<sub>2</sub> present as H<sub>2</sub>CO<sub>3</sub> but not as HCO<sub>3</sub><sup>-</sup> or CO<sub>3</sub><sup>2-</sup>.

Note: Atmospheric gases are present in seawater in approximately the following quantities:

	$ml\ l^{-1}$	Parts per million
Oxygen	0–9	0–12
Nitrogen	8–15	10–18
Carbon dioxide <sup>a</sup>	33–56	64–107
Argon	0.2–0.4	0.4–0.7
Helium and neon	$1.7 \times 10^{-4}$	$0.3 \times 10^{-4b}$

<sup>a</sup>Includes CO<sub>2</sub> present as H<sub>2</sub>CO<sub>3</sub>, HCO<sub>3</sub><sup>-</sup> and CO<sub>3</sub><sup>2-</sup><sup>b</sup>Estimated as helium

Concentrations of oxygen, nitrogen and carbon dioxide in equilibrium with 1 atm (101.325 kPa) of designated gas.

**Table 21.23** Properties of sea-water of different salinities

Salinity (‰)	Freezing point (°C)	Temperature of maximum density	Osmotic pressure (atm)	Specific heat (J kg <sup>-1</sup> )
0	0.00	3.95	0	$4.184 \times 10^3$
5	-0.27	2.93	3.23	$4.109 \times 10^3$
10	-0.53	1.86	6.44	$4.050 \times 10^3$
15	-0.80	0.77	9.69	$4.008 \times 10^3$
20	-1.07	-0.31	12.98	$3.979 \times 10^3$
25	-1.35	-1.40	16.32	$3.954 \times 10^3$
30	-1.63	-2.47	19.67	$3.929 \times 10^3$
35	-1.91	-3.52	23.12	$3.899 \times 10^3$
40	-2.20	-4.54	26.59	$3.874 \times 10^3$

**Table 21.25** Soil resistivities and corrosiveness

<i>Range of resistivity (<math>\Omega</math> cm)<sup>a</sup></i>	<i>Location</i>	<i>Soil type and classification</i>
10 000–100 000 and above	Perth, Scotland	Comparatively noncorrosive. Red sand-stone
8000–10 000	West Durham	Mildly corrosive. Sandstone and shale
Varying 1000–20 000	Staffordshire	Many built-up areas. Possibly very corrosive
1000–1500	Eastbourne, Sussex	Marshy ground. Very corrosive
15 000–20 000	Sussex Downs	Chalk. Non-corrosive
750–1500	Port Clarence, S.E. Durham	Salt marsh. Very corrosive
600–1500	S. Essex	Essex clay. Very corrosive
1400–3200	Newport, Gwent	Grey, yellow and blue clays, Corrosive
12 000–15 000	North Devon	Millstone grit. Comparatively non-corrosive
1000–2500	Gloucester	Generally clay. Corrosive
25 000–250 000	West Hampshire	Sandy gravel. Not generally corrosive

<sup>a</sup>To obtain  $\Omega$  m divide by 100.**Table 21.27** Corrosion-rate conversion factors

<i>Multiply</i>	<i>by</i>	<i>To obtain</i>
Milligrams per square decimetre per day ( $\text{mg dm}^{-2} \text{ day}^{-1}$ or mdd)	10	Grams per square metre per day ( $\text{g m}^{-2} \text{ day}^{-1}$ or gmd)
Inches per year (in $\text{year}^{-1}$ or ipy)	25.4	Millimetres per year ( $\text{mm year}^{-1}$ or mpy)

Ounces per square foot	3052	Milligrams per square decimetre ( $\text{mg dm}^{-2}$ )
Pounds per square foot per year	133.8	Milligrams per square decimetre per day ( $\text{mg dm}^{-2} \text{ day}^{-1}$ )
Grams per square metre per day	$0.36525/\rho$ ( $\rho$ in $\text{g cm}^{-3}$ )	Millimetres per year ( $\text{mm year}^{-1}$ )
Grams per square metre per day	$365.25/\rho$ ( $\rho$ in $\text{kg m}^{-3}$ )	Millimetres per year ( $\text{mm year}^{-1}$ )

**Table 21.28** Calculation of Corrosion rates of metals

The corrosion rate of a metal in terms of weight loss per unit area ( $\text{g m}^{-2} \text{ day}^{-1}$ ) or rate of penetration ( $\text{mm year}^{-1}$ ) can be calculated from Faraday's law if the current density is known. Conversely, the corrosion current density can be evaluated from the weight loss per unit area or from the rate of penetration. The following symbols and units have been adopted in deriving these relationships in which it is assumed that corrosion is uniform and the rate is linear:

$m$  = Mass of metal corroded (g)

$M$  = Molar mass ( $\text{g mol}^{-1}$ )

$z$  = Number of electrons involved in one act of the corrosion reaction

$F$  = Faraday's constant, 96 487 C ( $1 \text{ A} = 1 \text{ Cs}^{-1}$ )

$I$  = Current (A)

$i$  = Current density ( $\text{A cm}^{-2}$ ) and  $i = I/S$

$t$  = Time (s)

$\rho$  = Density of metal ( $\text{g cm}^{-3}$ )

$S$  = Area of metal involved ( $\text{cm}^2$ )

$d$  = Thickness of metal removed (cm)

From Faraday's law the weight loss per unit area is

$$\frac{m}{S} = \frac{Mit}{zF} (\text{g cm}^{-2}) \quad [21.1]$$

Since  $m = \rho Sd$ , then from eqn [21.1]

$$\rho Sd = \frac{Mit}{zF} \text{ or } \rho d = \frac{Mit}{zF} \quad [21.2]$$

and from eqn [21.2] the rate of penetration  $d/t$  when  $I$  is in  $\text{A cm}^{-2}$  is given by

$$\frac{d}{t} = \frac{Mi}{\rho zF} (\text{cm s}^{-1}) \quad [21.3]$$

If the c.d.  $i'$  is in  $\text{mA cm}^{-2}$ ,  $d$  in mm, and  $t$  in years, then

$$\frac{d}{t} = \frac{10^{-1}}{365 \times 24 \times 60 \times 60} = \frac{Mi'}{\rho zF} \times 10^{-3} (\text{mm year}^{-1})$$

$$\therefore \frac{d}{t} = 3.2706 \frac{Mi'}{z\rho} (\text{mm year}^{-1}) \quad [21.4]$$

To convert rate of penetration into weight loss per unit area per unit time:

$$(\text{gm}^{-2} \text{ day}^{-1}) \times \frac{0.36525}{\rho} = (\text{mm year}^{-1})$$

To convert c.d. ( $\text{mA cm}^{-2}$ ) into gmd:

$$(\text{gm}^{-2} \text{ day}^{-1}) = 3.2706 \frac{Mi'}{z\rho} \times \frac{\rho}{0.36525} = 8.954 \frac{Mi'}{z} \quad [21.5]$$

If  $i''$  is the current density in  $\mu\text{A cm}^{-2}$

$$(\text{gm}^{-2} \text{ d}^{-1}) = 8.954 \frac{Mi''}{z} \times 10^{-3} \quad [21.6]$$

## Glossary

**Conservation** Preservation of cultural heritage.

**Dense corrosion product layer (DPL)** The corrosion layer on archaeological iron objects that approximates to the original shape of the metal lost.

**Interventive conservation** Preservation strategy that involves physical or chemical change to an object.

**Marker layer** The layer of corrosion that approximates to the original position of the metal surface.

**Preventive conservation** Preservation strategy that utilizes techniques that do not involve physical or chemical change to an object.

## Abbreviations

**BTA** Benzotriazole

**CD** Current density

**CSS** Confederate Southern States

**DPL** Dense corrosion product layer

### 4.43.1 Introduction to Conservation of Metals

#### 4.43.1.1 Cultural Heritage Context

Cultural heritage is an industry that significantly contributes to the economy of nations via tourism, employment, and taxation. Whole communities rely on it for their economic welfare. Cultural objects and structures document developments and events within a society, offering a bridge to the past and providing important markers for individuals, religions, and cultures. To continue their contribution to the welfare, stability, development, and understanding of societies, cultural objects must be actively preserved. Age, origin, and use mean

that historical, archaeological, industrial, and art objects are often decayed, corroded, and prone to further deterioration. The diversity of contexts from which cultural heritage metals originate presents a significant preservation challenge. This chapter briefly defines conservation and provides an insight into the goals and ethical constructs that underpin its decision-making rationale. This is followed by an overview of how corrosion processes relate to treatment design and assessment. Conservation strategies for metals are revealed using selected examples of treatments to illustrate conservation research and practice.

Metals conservation involves the preservation of cultural objects and conservators are its practitioners. Their goal is to preserve objects while retaining evidence of their cultural context and integrity. Ideally there should be minimum change to an object while achieving this and restoration to the former state is rarely carried out. Refinishing, replacement of parts and repairing of metal objects with new corrosion-resistant materials are not normally options within the conservation process. While preservation appears to be a straightforward material science problem, involving elucidation of the structure and corrosion of metals to develop conservation procedures that prevent or control corrosion, it is constrained by ethics, aesthetics, and cultural contexts that may complicate, constrain, and ultimately direct preservation strategies.<sup>1</sup> The goal of conservation is normally the preservation of an object using minimum intervention, although in some instances arguments for partial or total restoration are valid and professional guidelines aid rationalization here.<sup>1</sup>

Research into the corrosion and conservation of historic and archaeological metals is developing significantly due to the increasing contribution of dedicated specialists and funding of large collaborative research programs that have a specific focus<sup>2,3</sup> and the challenges of large complex objects. An influx of corrosion scientists has improved the methodology of research and the understanding of conservation methods by widespread introduction of electrochemistry into corrosion and treatment studies.<sup>2-4</sup> As conservation is a blend of art and science, it utilizes data and publications generated by many disciplines to devise its preservation strategies. Literature sources within conservation focus mainly on conference proceedings and research project publications dedicated to specific themes that provide discussion forums for developing, interpreting, and reporting metallic corrosion and the conservation process. Metals conferences are organized and published by national conservation groups, museums, universities, and the International

Council for Museums Committee for Conservation Metals Working Group (ICOM-CC Metals WG). The Triennial Conference Proceedings of the ICOM-CC Metals WG provide the main dissemination route for metals corrosion and treatment research. This is supplemented by a web-based newsletter Bulletin of Research on Metals Conservation (BRO-MEC).<sup>5</sup> There are few textbooks that either specifically address metals conservation or contain significant sections dedicated to it.<sup>6–8</sup> A number of conservation journals report metals conservation and amongst these are *Studies in Conservation* and *Reviews in Conservation* published by the International Institute of Conservation; *Journal of the American Institute for Conservation*; *The Conservator* (Journal of the Institute of Conservation); and the German *Arbeitsblätter für Restauratoren*.

#### 4.43.1.2 Conservation: Definitions and Rationale

##### 4.43.1.2.1 Conservation rationale

Conservation of metals can be broadly split into interventive methods, which involve adding or removing something from an object in order to preserve it, and preventive techniques that aim to prevent corrosion by controlling the environment.<sup>1,9</sup> Both approaches require an understanding of the physical and chemical structure of metals, their interaction with environmental variables and the properties of their corrosion products. This information is used to design safe storage environments and to develop, implement, and assess interventive treatments. Conservation does not have its own universally defined preservation standards and generally works towards goals generated to satisfy prevailing situations.

##### 4.43.1.2.2 Preservation goals

The ultimate conservation goal of indefinite preservation has driven conservation rationale for many years. Stabilization is a much used word in conservation literature and a reassessment of its meaning and context are long overdue. Since few metals are inherently stable in ambient conditions, corrosion prevention for metals and alloys requires some degree of environmental control.<sup>9</sup> Depending on the degree of control required, significant capital outlay and ongoing energy consumption may be called for. This will carry a carbon footprint and may be beyond the financial means of many museums. Qualitative and quantitative control of environmental parameters, backed by relevant research to identify the environmental needs of the metals in question, underpins the concept of preventive conservation. Unstable metals are merely prevented from corroding using environmental control

and they remain inherently unstable. Since they have not been stabilized by an interventive treatment, any changes to the environment could once again favor their decay. This minimalist approach to preservation is now much favored in conservation practice. Previously, environmental control was normally employed as the end point of an interventive process focused on enhancing the chemical and physical stability of an object by attempts to remove corrosion accelerators and apply coatings and inhibitors. Interventive treatments should only be used where there is evidence that they enhance the stability and lifespan of an object without contravening ethical guidelines.<sup>1</sup>

Preservation strategies should be designed to support the role and function of the object in a society. This may involve public accessibility, which will require provision of oxygen, light, and heat. All of these are agencies of decay that can contribute to corrosion. Access to metal objects may mean it is necessary to accept the concept of limited lifespan, although this will depend on the metal in question and its condition. Alternatively, never viewing an unstable metal object while knowing it is preserved in deoxygenated storage may be an acceptable preservation strategy if the mere knowledge of its existence is sufficient for it to fulfill its cultural role. This may be the case for iconic objects that form cultural cornerstones within societies and history timelines.

##### 4.43.1.2.3 Standards in conservation

Few defined preservation and test standards exist within conservation at the time of writing (2008). The concept of indefinite preservation still pervades conservation thinking for metals. A move towards a rationale that pragmatically measures conservation outcomes as a function of resources, treatment success, cost, and object context is required to facilitate the defining goals that can be used to create standards. To produce attainable standards requires research that provides quantitative evidence of the success of treatment. Within metals conservation there is currently limited quantitative data that could be translated into hard currencies of object longevity, stability, and survival.

Standards grow from attainable and reproducible quantified outcomes. Gaps in our understanding of corrosion processes, treatment mechanisms, and treatment success hinder the production of conservation standards. There is a need for more research that definitively identifies corrosion mechanisms, quantifies treatments and measures their success relative to defined goals. International agreement on what constitutes realistic treatment success is required, as is a

recognized body that defines or approves standards with the support of the conservation profession. Thus, if a standard does not prevent decay there must be an indication as to the extent to which it protects from corrosion or prolongs lifespan. This requires a definition of lifespan reliant upon identifying the function of a cultural object and defining when it ceases to fulfill this function. These are difficult questions but until they are answered conservation cannot develop models that quantitatively define goals and offer a framework of standards to achieve them. There is a case for the conservation profession to devise its own standards for use in research and quality assurance, as ISO and ASTM standards are often inappropriate for use in conservation research and practice.

#### 4.43.1.2.4 Ethics

Ethics both guide and constrain conservation practice. National guidelines define generic rules for good practice that include minimum intervention with objects, reversibility of conservation materials and of treatments applied to cultural objects, as well as retention of the cultural integrity of an object and the information it contains.<sup>1</sup> Situation ethics prevail when determining the level of intervention required to preserve objects. Within archaeological conservation, significant intervention is normally essential for understanding the technology and function of a metal object or for revealing its shape from a corroded metal conglomerate. Ethical dilemmas abound when devising treatment procedures. While a blistering paint surface on a working engine comprising cast iron and steel might be removed and the surface repainted to approved international standards, accessioning such an object into a museum changes this and the paint now constitutes part of the object history. An ethical preservation process for such an object might involve the local stabilization treatment of pits in the paint layer, followed by application of an unobtrusive protective coating and storage in a controlled relative humidity. This is more expensive to execute and offers a less predictive corrosion control strategy than stripping the metal to an SA standard and repainting.

### 4.43.2 Corrosion

#### 4.43.2.1 The Influence of Corrosion on Conservation Strategies

The nature and extent of corrosion strongly influences conservation strategies. Understanding how metals corrode within specified environments such as museum interiors, enclosed storage boxes and the

atmosphere is central to developing treatments and identifying realistic conservation goals. It may be necessary to understand more than one corrosion model to devise conservation procedures. For instance, understanding how archaeological metals corrode during burial is essential for developing a model of their corrosion in the atmosphere following excavation. Equally, elucidating the corrosion mechanisms on a historical pewter salt cellar facilitates an understanding of how this object corrodes in a museum environment. It may no longer contain salt, but the legacy of its original function influences its future survival. Corrosion models also contribute to understanding object aesthetics and developing conservation ethics. Research into corrosion mechanisms informs conservators about the stability of objects, their rate of decay and their conservation needs.<sup>2</sup>

#### 4.43.2.2 Corrosion of Archaeological Metals

Although reviews of archaeological and historical metal corrosion exist,<sup>10</sup> aspects of corrosion relevant to the treatments discussed here are briefly outlined. Archaeological metals normally corrode extensively during burial to form corrosion products related to their burial environment and alloy composition.<sup>2,6,7,9,10</sup> Environment, alloy composition and the mechanisms of ionic and electron transfer during corrosion dictate the nature of the corrosion layer formed and whether corrosion products are passive or unstable. Smooth dense patinas or voluminous disfiguring corrosion layers may form. Some corrosion layers can retain good approximation of the shape of the object and surface details like wear marks or engraving<sup>2,6,7,9,10</sup> (see [Figure 1](#)). These layers have been loosely referred to as representing the original surface of the object<sup>2,7</sup> but are now more often called marker layers.<sup>2</sup> They are often hard and compact and may be overlaid with softer more voluminous corrosion.

Conservation is not just about preservation. Archaeological metals are subjected to investigative conservation that involves analysis designed to answer questions on technology, provenance, and trade.<sup>1,7</sup> Mechanical cleaning employing hand tools like scalpels and micro air abrasion techniques, which utilize powders such as aluminum oxide, are often employed to remove overlying corrosion to reveal the marker layer. Guidance in this process is helped by X-radiography. By detecting differences in density juxtaposition of differing corrosion products are shown, along with dissimilar metals, technological detail and evidence

of residual metal<sup>7</sup> (see [Figure 2](#)). This information-sensitive marker layer may be physically weak and infused with soluble corrosion accelerators, but it must remain undamaged by any treatment, whether it has

**Figure 1** Corrosion products can sometimes retain significant surface detail. Lead and tin corrosion products record an assay mark in an archaeological pewter object (a) and a Roman copper alloy stud retains wear mark scratches in its fine smooth patina (b).

been revealed or is left covered with corrosion products. Chemical treatments that strip off all corrosion products to remove the soluble corrosion accelerators they contain cannot be used to treat archaeological metals, as the remaining metal rarely represents the original shape of the object<sup>7</sup> (see [Figure 3](#)).

Post-excavation corrosion processes usually differ from those occurring in the burial environment, as the atmosphere contains more oxygen and is normally less damp than soil.<sup>2,10</sup> To develop a preservation plan it is essential to understand how the corrosion model changes, especially how corrosion products form in the burial environment, respond to the new environment and influence the metal they are associated with.

The instability of archaeological iron offers a clear example of how an understanding of corrosion mechanisms is essential to treatment design. It is used here to illustrate conservation thought processes for metals containing soluble corrosion accelerators. During burial, chloride is attracted to anodes as a counter ion to balance charge from  $\text{Fe}^{2+}$ .<sup>2,10</sup> In damp burial conditions it exists as a  $\text{Fe}^{2+}/\text{Cl}^-$  solution at the metal surface. Chloride content may be typically 0.1–1.5 wt % of object, but can be significantly greater for marine metals<sup>7,10–12</sup>. Soluble chloride acts as an electrolyte making the iron inherently unstable. Overlying the corroding metal core is a dense corrosion product layer (DPL) identified as comprising a goethite ( $\alpha\text{-FeOOH}$ ) or sometimes a siderite ( $\text{FeCO}_3$ ) matrix in which are embedded magnetite ( $\text{Fe}_3\text{O}_4$ ) or maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ) strips<sup>2</sup> (see [Figure 3](#)). This is effectively the marker layer for the surface of the object and is also present in totally mineralized objects, which present no ongoing corrosion problem, but remain a conservation problem due to their fragility and the need to reveal their original shape.

Moisture and oxygen in the post-excavation environment facilitates the formation of  $\beta\text{-FeOOH}$

**Figure 2** X-radiography records the presence of a dissimilar metal inlay (silver) hidden under corrosion of uneven density on this Roman Scabbard. The density distribution on the radiograph indicates that no metallic iron remains.

**Figure 3** A cross section of a medieval nail shows it retains a substantial metal core and differing corrosion layers (a). Images (b) and (c) show how the dense corrosion product layer (DPL) retains the shape of the nail, which is overlaid with a corrosion matrix containing soil. Stripping the nail of all corrosion would lose the shape of the object and its surface detail. Totally mineralized iron retains the shape of the object as a corrosion layer, visible in this Roman nail (d).

(akaganeite) in the acidic chloride rich solution sited at anodes on the metal surface. Chloride is incorporated into tunnels within the hollandite-type  $\beta$ -FeOOH crystal structure and adsorbed onto its surface.<sup>2,10</sup> Growth of these voluminous tower-like  $\beta$ -FeOOH crystals pushes off the overlying DPL and is catastrophic for the object as an information resource, as it destroys evidence of the original surface and shape leaving only an unevenly corroded metal core (see [Figure 4](#)). While conservation strategies aim to reveal the shape of the object they must also prevent the corrosion of metallic iron, as the consequent formation of  $\beta$ -FeOOH would remove the information retaining DPL. Totally mineralized iron is stable, as there is no more metal to oxidize and this has allowed soluble anodically held chloride to diffuse out of the object.

Corrosion of nonferrous archaeological metals presents different conservation problems. Most are alloyed with other metals as; bronze (copper/tin sometimes with added lead); brass (copper/zinc);

**Figure 4** Corrosion at the metal/DPL interface results in loss of overlying corrosion products and the information they contain.

pewter (lead/tin); and precious metals (silver/gold, silver/copper, gold/copper). This facilitates preferential corrosion.<sup>7,10</sup> Thus, gold may lose the copper it is alloyed with and be covered in copper corrosion

products. Chemically removing these copper corrosion products leaves a soft porous copper depleted layer of gold on the surface of the alloy. Mechanical removal of corrosion leaves copper corrosion products embedded in the metal surface alongside the gold, but produces a stronger surface.

Corrosion processes, products, and rates can vary according to the proportions of metal within alloys and the burial conditions. This can prove advantageous, although bronzes often decuprify the corrosion of alloyed tin, producing an insoluble and poorly mobile tin oxide to act as a marker layer for the original surface of the metal.<sup>2</sup> Lead forms very stable lead carbonates in neutral to alkaline burial conditions and insoluble chloride compounds that are stable following excavation.<sup>9</sup> Silver is also stable after excavation due to the highly insoluble silver chloride and silver sulfide formed on its surface.<sup>10,13</sup> Lead and tin have similar corrosion potentials and both corrode in pewter to produce a lamellar wart-infested surface with powdery corrosion products that are unlikely to form marker layers. Copper that forms sparingly soluble cuprous chloride ( $\text{CuCl}$ ) next to the metal surface can be unstable following excavation if there is sufficient water to hydrolyze it to voluminous  $\text{Cu}_2\text{OH}_3\text{Cl}$  known as ‘bronze disease.’<sup>2,6,7,8,10</sup> Conservation procedures will be dictated by the stability of the corroded metals, corrosion mechanisms, and the presence or absence of marker layers.

#### 4.43.2.3 Corrosion of Historical and Modern Metals

Historical metals are found in outdoor and indoor environments and may be decorative objects d’art, functional artifacts, or large industrial items. Metals kept indoors since their fabrication may have very little corrosion and retain their original surface finish. Conservation aims to retain such surfaces. This can be achieved by monitoring environments, simple good housekeeping and environmental control in relation to corrosion threshold values for the metals in question.<sup>1,9,14</sup>

The context of the object is important and the nature of a corrosion patina (see [Section 4.43.5.2](#)) may be seen as an important aesthetic value of the object or part of its life history. This will dictate whether it is removed or retained during conservation and heavily influences the choice and success of treatments. Analysis aids decision making in conservation. Sometimes it may be necessary to replace metals if they are performing a structural function. Analysis detected dezincification of brass (70:30) in nails used to join the planks in the hull of the yacht

Asgard (see [Figure 5](#)). Built in 1905 by Colin Archer the renowned Norwegian shipwright for Robert Erskine Chalders the yacht is now an important part of Irish history. The analysis provided information that aided conservation decisions for nails that otherwise appeared to have only surface corrosion.

Modern metals increasingly occur in museum collections and are the fabrication materials of many cultural icons and monuments. These include zinc, aluminum, magnesium, and their alloys.<sup>15</sup> Conservation of protective and technologically informative surface finishes on metals like aluminum may be equally as important as preserving the metal itself.<sup>16</sup> Air quality, relative humidity, and temperature are important for metal stability within museums. The Oddy test<sup>17</sup> was devised to determine if materials used to construct boxes and showcases give off gas pollutants that will cause metals within them to corrode over long-time periods. It can also be applied to show if metals and

**Figure 5** SEM/EDX mapping of zinc brass hull nails from the yacht Asgard revealed surface dezincification (a) which is not visible on the nail (b). This analysis contributed to designing the yacht’s conservation plan carried out at the National Museum of Ireland. (SEM scale bar 500 µm).

alloys corrode in polluted environments, thus aluminum and Duralmin (Al/Cu) corrode in the presence of formic acid and magnesium and AZ31 (Mg/Al/Mn/Zn alloy) corrode in the presence of a wide range of materials that include oak, plywood, formic acid and wool, which may all be found in museum environments.<sup>15</sup> Lead and copper are also susceptible to corrosion from carbonyl pollutants.<sup>2,9,10,18</sup> Equally studies must examine what occurs when objects are handled, as chloride corrosion products on zinc coins and Indian Bidri ware (zinc alloy) in museum collections were attributed to handling.<sup>15</sup> The influence of handling on corrosion is evident for tarnishing of silver by sulfur compounds, where fingerprints can act as a focus for corrosion (Figure 6). Conservation has moved some way towards developing standards for showcase design and the use of corrosion-safe construction materials, but much more remains to be done.

Outdoor corrosion patterns on metals are predominantly influenced by alloy composition, environment, climate, and the object morphology.<sup>19</sup> Out of doors iron produces a corrosion layer mostly comprised of loose  $\alpha$ -FeOOH rather than form the shape retaining DPL that occurs on archaeological objects<sup>2</sup> (see Figure 3). Sulfurous gases can produce a  $\text{FeSO}_4$  corrosion cycle that is humidity sensitive. While conservation of iron that has corroded in the atmosphere may involve removal of corrosion layers, rather than their retention, outdoor copper alloys may develop patinas considered to be aesthetically desirable and conservation planning takes account of this<sup>2,6</sup> (see Section 4.43.5.2). Humid air containing  $\text{SO}_2$  will attack copper alloys dissolving passive layers and supporting electrochemical corrosion of the alloy,<sup>19</sup> which is problematic

**Figure 6** The influence of a fingerprint on the pattern of sulfur tarnishing on this silver surface is clearly visible. A protective coating on the surface would have prevented this.

for statuary and architectural fittings. Establishing the precise role of patinas and corrosion product layers in the corrosion process is currently underway for many metals,<sup>2</sup> which will facilitate better long-term planning and improve treatment design.

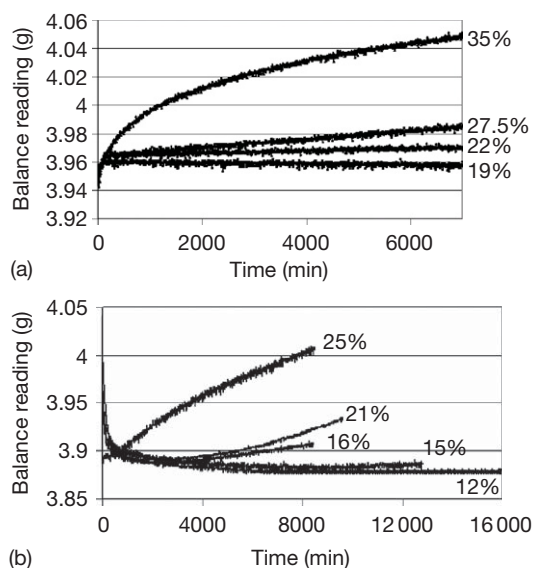

### 4.43.3 Environmental Control of Corrosion: Preventive Conservation

#### 4.43.3.1 Desiccation

A common preservation strategy for cultural metals is to prevent their electrolytic corrosion by controlling one of the agencies essential for this process to occur. Normally, removal of moisture is used to prevent electrolyte formation, although in some instances the oxygen necessary to support cathodic processes and form corrosion products is removed. Removal of electrolyte ions from corroded metals involves interventive treatment. It is easier, cheaper, and more user friendly to control corrosion by desiccation than to remove oxygen. The degree of desiccation necessary to prevent corrosion differs according to the corrosion mechanism of the particular metal or alloy and dictates the cost of corrosion control as capital outlay on plant, fuel, and personnel. Despite the importance of understanding corrosion mechanisms for optimizing preventive conservation strategy, only chloride infested iron has been extensively researched to identify relative humidity (RH) no-corrosion thresholds for reactions within its corrosion mechanism.

##### 4.43.3.1.1 Relative humidity – Threshold corrosion values

Ambient humidity can supply moisture to solvate ions within corroded metals and create electrolytes. Conservation of metals examines corrosion as a function of RH rather than absolute humidity.<sup>6,8,10,14</sup> It is well known that hygroscopic or deliquescent salts such as sodium chloride can lower the RH threshold for corrosion to occur.<sup>10</sup> The RH at which the formation of electrolytes begins is the threshold corrosion value.<sup>20</sup> On corroded iron the surface adsorbed chloride on hygroscopic  $\beta$ -FeOOH becomes mobile within atmospheric moisture and corrodes iron in contact with it at 15% RH<sup>20</sup> (see Figure 7). Additionally, ferrous chloride may form in the low pH and high  $\text{Fe}^{2+}/\text{Cl}^-$  environment created as damp chloride infested iron, dries<sup>10</sup> (see Figure 8). Any  $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$  that forms contains enough water to corrode iron in contact with it, but once  $\text{FeCl}_2 \cdot 2\text{H}_2\text{O}$  forms at 20%, RH corrosion ceases<sup>20</sup> (see Figure 7). Storage standards

**Figure 7** Relative humidity influences the corrosion of iron powder mixed with  $\text{FeCl}_2 \cdot 2\text{H}_2\text{O}$  (image 1) and  $\beta\text{FeOOH}$  (image 2); with no-corrosion points at low humidity and significant corrosion as 30% relative humidity is approached, as shown by weight gain due to oxidation. Initial weight loss (b) is due to dehydration of  $\beta\text{FeOOH}$  as it equilibrates with its environment.

for chloride infested iron at 20 °C have been defined as: at 12% RH no corrosion; 15–20% RH  $\beta\text{-FeOOH}$  causes slow corrosion of iron; above 21% RH both  $\beta\text{-FeOOH}$  and  $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$  contribute to corrosion<sup>20</sup> (see Figure 7). Corrosion increases significantly above 25%<sup>19–21</sup> and several times faster above 30% RH than at 25%.<sup>20,21</sup>

In contrast controlled storage of corroded iron from historical contexts has received scant attention in conservation research, as it will tolerate higher humidity values before incurring corrosion if it is chloride free. No conservation studies have examined how iron contaminated with sulfates from  $\text{SO}_2$  pollution would respond to RH.

Corrosion of archaeological copper alloys can occur when cuprous chloride ( $\text{CuCl}$ ) close to the metal surface hydrolyses to form basic cupric chloride ( $\text{Cu}_2\text{OH}_3\text{Cl}$ ) polymorphs, usually clinoatacamite or atacamite with an accompanying molar volume increase.<sup>6</sup> This pressures or undermines the overlying hard and dense corrosion layers that predominantly comprise malachite ( $\text{CuCO}_3 \cdot \text{Cu(OH)}_2$ ), breaking their contact with the  $\text{CuCl}/\text{Cu}_2\text{O}$  mixture next to the metal and ultimately causing their exfoliation. Scott<sup>6</sup> observed no reaction over the relative humidity range 42–46% but rapid corrosion at 70%, leading him to recommend storage below 45% relative humidity in

contrast to the anecdotal 39% commonly cited in conservation. The  $\text{CuCl}/\text{Cu}$  corrosion model merits closer scrutiny to define both the critical no-corrosion humidity and corrosion rates above this value.

Unless it has been already corroded by aggressive ions such as chloride and sulfate, aluminum offers minimal conservation challenges provided it is stored at around 55% relative humidity.<sup>16</sup> Reaction of chloride infested aluminum alloys to relative humidity has not been examined in relation to safe storage thresholds. Similarly, the role of soluble tin chlorides in the corrosion of tin and tin alloys merits detailed study, since tin chloride solutions are prone to hydrolysis.

#### 4.43.3.1.2 Practical humidity control

Humidity control either employs active dehumidification using mechanical plant or passive desiccation using desiccants like silica gel to control environment in fixed storage or display areas.<sup>9,14,21–23</sup> A significant advantage of controlling corrosion of cultural metals by desiccation is that they remain easily accessible, especially if an entire store room is desiccated as opposed to individual storage boxes. Although maintaining low humidity using mechanical desiccation plant demands finance and energy, it is capable of controlling large spaces that will require only one or two telemetric sensors to monitor relative humidity. These can immediately and remotely detect any failure to maintain target relative humidity on a macroscale, which allows for rapid remedial response. Thus mechanical corrosion control is a low risk corrosion control strategy for cultural metals, provided resources exist to underpin its continuing operation and management.

In contrast the small scale control of climate by silica gel for storage within enclosed polyethylene boxes and for display in sealed showcases appears to offer a cheap conservation strategy for small metal objects. Gradual hydration of the desiccated silica gel will occur as a function of air exchange rate, external relative humidity and initial moisture content of the metals being desiccated.<sup>21–24</sup> This eventually raises internal humidity within the controlled space to values that support corrosion, which will speed up as internal relative humidity continues to rise until it equilibrates with the external environment. The metals now rest in a continually aggressive environment. Determining when to replace the silica gel relies upon knowing the threshold corrosion value of the metals in question and detecting when the interior of the box exceeds this value.

Research to evaluate the complex equation of storage, hardware performance, air exchange, monitoring, maintenance time, and human error is needed

**Figure 8** Brunel's iconic SS Great Britain was the first ocean going screw driven iron hulled passenger liner and is now preserved by a mechanical desiccation system that maintains relative humidity to 20% and allows visitors to walk around the hull. Reproduced from Watkinson, D.; Tanner, M.; Turner, R.; Lewis, M. *The Conservator* **2005**, 29, 73–86.<sup>25</sup>

to offer a realistic and practical assessment of this corrosion control strategy. Enclosure design largely controls air exchange rate which is the governing factor in passive desiccation systems.<sup>24</sup> Assessment of enclosure performance can produce predictive life spans for specified passive desiccation storage systems.<sup>21,24,26</sup> Showcases designed for desiccation maintained relative humidity below 20% for 1 year without a change of their silica gel desiccant, when external relative humidity fluctuated between 60% and 95%.<sup>22,24</sup> As telemetric monitoring of showcase

performance is easy to initiate and financially viable, this system offers potentially reliable low energy consumption corrosion control for unstable metals on display. The major cost will be an initial outlay to meet the showcase specification. Further work could establish performance of the showcase with age and use. This requires real-time testing that may take several years. Attempting to define long-term effectiveness by extrapolating a one year study or short-term laboratory results cannot provide a definitive guide to performance.

The performance of polyethylene storage boxes as desiccated depositories for archaeological iron has been studied as functions of manufacturer, age, use, silica gel performance, and ambient relative humidity.<sup>21</sup> The study confirmed earlier studies on threshold corrosion values<sup>20</sup> and determined most air leakage was via lid seals, making storage protocols important in relation to the stacking of boxes compromising their seals. Storage in polythene boxes suffers from a reliance on the limited accuracy of moisture sensitive indicators to detect the internal relative humidity of boxes for gel regeneration cycles. Individual telemetric monitoring of the interior of the box is financially prohibitive for the several hundred polyethylene boxes normally housed in a storeroom. Good management is also necessary if the gel is to be changed as required. It is essentially a low cost, but high risk corrosion control strategy when the frailties of human nature are taken into account.

Relating corrosion rate to increasing relative humidity provides opportunity for pragmatic management decisions.<sup>25</sup> The degree of corrosion control implemented can be matched to resources available to produce a package that will reduce, but not prevent corrosion. This reasoning was used to control corrosion of Brunel's famous 1843 wrought iron steamship SS Great Britain, whose chloride-ridden lower hull is preserved in a mechanically desiccated dry dock maintained at 20% relative humidity with a goal of retaining its structural integrity for at least 100 years<sup>25</sup> (see [Figure 8](#)). This allowed public access to the hull and avoided employing costly and environmentally unfriendly alkaline washing methods (see [Section 4.43.4.2](#)) in attempts to remove chloride corrosion accelerators from the 324 ft long hull. The conservation challenge required a scientific investigation to identify the influence of RH on corrosion, followed by an engineering project to design an envelope to maintain the operating RH.

#### 4.43.3.2 Deoxygenation

Ageless™ is a commercial oxygen absorber that has been used in conservation to deoxygenate enclosed spaces.<sup>26</sup> It is expensive to use and the exothermic reaction that expends oxygen produces water, which should offer no corrosion risk provided the storage environment remains oxygen free. Despite technical challenges, high cost, and reduced accessibility, archaeological iron has been stored in heat sealed low linear density polyethylene tube, with barrier properties 2000 times better than polypropylene, deoxygenated with

oxygen scavenging RP-A™ (mordenite/CaO/PE/activated carbon).<sup>27</sup> This study showed that iron objects, which had been pretreated in aqueous NaOH to wash out chloride (see [Section 4.43.4.2](#)), remained visibly unchanged over a 5-month period but untreated iron had a 12% failure rate attributed to poor seals and bag punctures. Although the researchers predict a storage lifespan of 4–6 years, the high initial cost of materials and labor and a one-shot storage system make it unlikely that it will displace desiccation in popularity. A long-term quantitative testing program comparing its effectiveness, ease of use and global cost with desiccation techniques would define the relative merits of these two treatments. Using a flow of nitrogen gas through an enclosed container offers a no-corrosion environment for damp high status archaeological objects prior to their conservation.

### 4.43.4 Interventive Treatments

#### 4.43.4.1 Removing Ions that Act as Corrosion Accelerators

Interventive treatments aimed at reducing or preventing corrosion of unstable metals mostly focus on removing chloride and other soluble ions that are capable of acting as electrolytes in high humidity environments. Entirely removing soluble ions should prevent corrosion, while their partial removal enhances the stability of the object by reducing electrolyte availability. Additionally, some washing treatments may aim to remove or modify sparingly soluble or insoluble corrosion products that promote corrosion.<sup>11,28</sup>

From an ethical standpoint, merely enhancing stability without controlling environment to prevent corrosion may not be considered an appropriate corrosion control strategy. Even a small amount of corrosion occurring at anode sites on the metal can interfere with adhesion of important overlying corrosion layers, whose loss destroys the object as an information resource despite the survival of the metal core (see [Figures 2–4](#)). Delaying this for a short time by reducing corrosion rate could be viewed as a very limited goal, when measured against the ideal of indefinite preservation. Equally, treatments that partially remove corrosion accelerators could be seen as unnecessary, since post treatment storage must be similar to that provided for untreated metals. Why bother trying to remove electrolytes if the objects still need to be subjected to the same stringent storage conditions? One possible advantage is that failure to maintain the controlled environment will lead to a slower corrosion

rate, as compared to untreated iron objects. Quantitative understanding of treatment efficiency and effectiveness is essential for facilitating informed decisions about their use.

To optimize treatments designed to remove corrosion accelerators that are normally predominantly comprised of chlorides, it is necessary to: identify the corrosion mechanism; devise appropriate chloride removal procedures; quantify the removal of chloride as an absolute value of chloride contained in the metal; use this value to calculate extraction efficiency; determine the extent to which the metal is stabilised.<sup>11</sup> While the concept of removing soluble ions to prevent electrochemical corrosion is logical, no studies provide quantitative assessment to show how stable metals like iron become following attempts to remove their soluble chloride. Equally, there is limited information as to what percentage of chloride present within objects is extracted by a particular treatment and how consistently this occurs.<sup>11,12,29</sup>

#### 4.43.4.2 Washing Methods in Practice

Washing methods are applied to metals to solvate soluble corrosion products and soluble ions adsorbed onto corrosion products. Iron is the most unstable archaeological and historical metal, due to its ability to attract chloride and retain it in a highly soluble form.<sup>10</sup> Washing methods will solvate chloride ions and this allows them to diffuse out of the object.<sup>7,11</sup> This process is hampered by the DPL limiting solution access to the iron surface, where wash solutions must enter pits and micro cracks to exchange with chlorides at anode sites. Chloride removal is diffusion controlled, slow, and is unlikely to be 100% efficient, although efficiency can be improved using chemical additives.<sup>11,12,29</sup> Evidence from a qualitative study of the long-term stability of treated archaeological iron revealed simple washing with hot deionized water to be a poor stabilization system, with 68% of treated objects recorroding.<sup>30</sup> Recent study quantitatively confirms washing in deionized water is an unpredictable treatment that never extracts large amounts of chloride<sup>11</sup> (see Figure 9).

Their ease of use and low aggression to iron has meant that inhibited wash solutions have been chosen to treat large objects. HMS Holland was the first submarine used by the British Navy. It was fortunate that she lost her tow en route to the breakers yard and sank, as when she was discovered and salvaged many years later she had become an important historical object. Her 19 m length offered challenges to removing the

**Figure 9** Influence of treatment solution on percentage chloride removal from Roman and Medieval archaeological iron nails. For each treatment method columns show: best extraction; average extracted; worst extraction. Total chloride in nails determined by post treatment digestion. Treatment methods: (1) NaOH/Na<sub>2</sub>SO<sub>3</sub> 0.5 M aq. (17 nails); (2) NaOH 0.5 M/deoxygenated with nitrogen (10 nails); (3) NaOH 0.5 M aq. (16 nails); (4) Water/deaerated with nitrogen (10 nails); (5) Water (10 nails). Reproduced from Watkinson, D.; Al Zaharani, A. *The Conservator* **2008**, 31, 75–86.

chloride that infused her structure. Health and safety and cost augmented against the use of strongly alkaline wash treatments (see below) and electrolytic desalination (see Section 4.43.4.3). A purpose built treatment tank containing 820 000 dm<sup>3</sup> of Na<sub>2</sub>CO<sub>3</sub> was used to provide an inhibited wash relying on diffusion to extract chloride that was continually monitored.<sup>31</sup> Treatment was followed by storage in a building constructed for this purpose maintained at 35% RH to slow down any corrosion from residual chloride. While new study indicates storage at 25% RH would slow iron corrosion significantly more than 35% RH,<sup>11,20,21</sup> any environmental control program must be related to the finance available to sustain it and 35% RH will restrict corrosion better than higher values. This is a typical finance/corrosion control cost benefit assessment that is a factor in the conservation equation. It is often used to influence selection of treatment options and should be considered when developing standards of treatment. Equally object size may dictate which treatments are feasible, as in the case of the Holland.

Alkaline wash systems act as inhibitors and optimize chloride removal.<sup>8,11,12,29</sup> Inhibition provided by alkalis such as NaOH reduces corrosion during treatment. This releases chlorides from their charge balancing role at anodes and allows them to diffuse out into the wash solution, while at the same time the alkali supplies OH<sup>−</sup> ions to replace them and associate with Fe<sup>2+</sup>. Solvation of solid ferrous chloride and surface adsorbed chloride on β-FeOOH occurs,

reducing  $\beta$ -FeOOH hygroscopicity and preventing post-treatment corrosion of iron in contact with it.<sup>32</sup> In strong alkali  $\beta$ -FeOOH can transform and this will advantageously release chloride into the wash solution.<sup>28</sup> Since the ionic size of chloride occluded in tunnels within  $\beta$ -FeOOH crystals exceeds the diameter of tunnel entrances it remains trapped and presents no post-treatment corrosion threat, unless conversion of  $\beta$ -FeOOH to  $\alpha$ -FeOOH releases this chloride. Post-treatment hydrolysis of residual  $\beta$ -FeOOH to  $\alpha$ -FeOOH can occur but is little studied. A 23-year-old dry sample of  $\beta$ -FeOOH was assayed as being 1%  $\alpha$ -FeOOH and 99%  $\beta$ -FeOOH.<sup>32</sup> A major study currently underway aims to identify physicochemical transformations of corrosion layers as a function of treatment regimes, using microanalysis techniques to characterize the corrosion products.<sup>33</sup> This will significantly contribute to an understanding of treatment and post-treatment corrosion.

Further improvements in chloride extraction can be produced by deoxygenated NaOH solutions<sup>11</sup> (see Figure 9). Passivation of iron in oxygenated NaOH solutions is likely to be incomplete, as NaOH needs to reach all anodes sited at the metal surface to be effective. Consequently, chloride continues to be held as a counter ion and is difficult to wash out. Deoxygenating NaOH solutions with an  $\text{SO}_3^{2-}$  oxygen scavenger or nitrogen gas stops corrosion and improves chloride extraction.<sup>11</sup> Anecdotal reporting indicates undesirable softening of corrosion products in NaOH solution,<sup>30,34</sup> but no studies offer quantitative evidence of this or address the influence of any chemical treatment residues on iron corrosion products. This merits further attention. Objects should be washed post-treatment in deoxygenated water to flush out chemicals.

A promising variation on alkaline washing currently under investigation is the use of a subcritical high pressure alkali treatment for treating the American Civil War submarine Hunley, which was recovered from a marine environment where she had lain since she sank immediately after becoming the first submarine to sink a warship.<sup>12,29</sup> Treatment transforms corrosion promoting  $\beta$ -FeOOH to the  $\alpha$ -FeOOH,  $\text{Fe}_3\text{O}_4$ , and  $\text{Fe}_2\text{O}_3$  chloride-free phases that are nonaggressive to iron.

Other inhibitors have been tried, notably aqueous washing of archaeological iron with ethylene diamine. Inhibition and a high solution pH (11.5 at 5% (v/v) aq.) aim to prevent corrosion during treatment and aid chloride removal. It is an inferior chloride extractor as compared to 2% NaOH aq.,<sup>34</sup> but has been cited as offering good long-term stability to iron in a qualitative study of treated objects.<sup>30,34</sup>

There is limited information available regarding the amount of chloride removed by treatments as a function of total chloride within the iron, since determining residual chloride requires post-treatment digestion of objects. The small amount of quantified data available indicates that some wash methods are significantly better than others and consistently extract within fixed percentages of chloride.<sup>11,12,29</sup> The limit of detection for measuring chloride extracted into wash baths cannot guarantee iron is chloride free.<sup>11,12</sup> Although it is important to determine whether small residues of chloride are capable of causing significant corrosion of iron, testing the susceptibility of washed iron to corrosion has received little attention. For guaranteed no-corrosion all washed iron should be stored in a controlled environment to a standard equaling that used for unwashed iron, but this makes storage costs the same as for untreated iron.

Studies that qualitatively examine the stability of washed and unwashed iron within museum collections have offered comparative assessment of treatment effectiveness.<sup>30,35,36</sup> While these types of survey offer a genuine insight into treatment outcomes, they are limited by their retrospective nature, wide range of uncontrolled variables and a lack of quantified data. Computer monitoring of RH now offers an opportunity for precise recording of storage environment and new studies of long-term performance of treated objects are overdue. It would also be worth interpreting past studies using new data available on corrosion mechanisms.<sup>2</sup> Until quantitative long-term post-treatment stability testing is carried out and outcomes are linked to chloride residues within objects, washing treatments remain empirical applications best described as having an unpredictable and unknown capacity to remove chloride and enhance object stability. Such studies will prove hard to fund because of their time commitment.

Aluminum alloys are becoming increasingly common in museum exhibits and include aircraft and boats rescued from extreme environments. Once the highly protective nonconducting  $\text{Al}_2\text{O}_3$  layer on aluminum fails the metal will corrode. This may cause pitting or intergranular corrosion according to alloying and metallography. Chlorides exacerbate corrosion by attacking the  $\text{Al}_2\text{O}_3$  film and concentrating in pits where they cause low pH, hydrolysis of  $\text{Al}^{3+}$  and voluminous disfiguring corrosion product at the mouth of the pit.<sup>10</sup> The shape of the object is obscured and ultimately lost with eventual perforation of the metal. Washing to remove soluble chloride can be carried out on objects retaining significant amounts of metal, but those without large quantities of metal

will be beyond recovery as corrosion products are non-adherent and friable.

Chemically aided washing was innovatively used to treat a Duralumin (3–5% copper) seaplane float belonging to a Junkers W33 infused with chloride, exhibiting extreme pitting and redeposited copper on its surface that could act as a cathode for continuing corrosion of the aluminum.<sup>37</sup> Washing conditions were carefully manipulated using  $(\text{NH}_4)_2\text{SO}_4/\text{NH}_3$  buffer solution to complex  $\text{Cu}^{2+}$  ions to  $\text{Cu}(\text{NH}_3)_4^{2+}$  and  $E_0$  of the system was lowered to allow corrosion that removed redeposited copper, provided oxygen was present.<sup>37</sup> Thermodynamic data revealed  $\text{Al}_2\text{O}_3$  was stable in the treatment solution. Its presence on the metal surface protected aluminum at the treatment pH of 9.6 and chloride diffused out of the object following hydrolysis reactions within pits. As with most washing methods employed in conservation, assessment of the success of the treatment was qualitative and reported that the object appeared to be stable 4 months after treatment.

Washing has been employed for copper alloys to deal with the problem of  $\text{CuCl}$  hydrolyzing to form  $\text{Cu}_2(\text{OH})_3\text{Cl}$  polymorphs that damage and disfigure copper alloy objects.<sup>6,10</sup> Fortunately  $\text{Cu}_2(\text{OH})_3\text{Cl}$  is not hygroscopic and does not cause corrosion of metallic copper in contact with it, although its growth can undermine and lever off overlying patina. Not all copper alloys containing chloride are unstable. MacLeod<sup>38</sup> argues that there is a minimum chloride ion concentration required to support corrosion. The low solubility of  $\text{CuCl}$  and its positioning within or under  $\text{Cu}_2\text{O}$  means chloride solvation by simple aqueous washing can last years. Washing for up to 2 years in sodium sesquicarbonate ( $\text{NaHCO}_3 \cdot \text{Na}_2\text{CO}_3$ ) at 5% (w/v) pH 10 has been employed to slowly solvate  $\text{CuCl}$  and supply  $\text{OH}^-$  to form cuprous oxide ( $\text{Cu}_2\text{O}$ ).<sup>6,9</sup> Basic copper carbonate ( $\text{CuCO}_3\text{Cu}(\text{OH})_2$ ) and chalconatronite  $\text{Na}_2\text{Cu}_2\text{CO}_3 \cdot 2\text{H}_2\text{O}$  may also form and darkening of patina may make the treatment undesirable when aesthetics are an important consideration. It is now more likely to be used as an inhibited wash solution following other treatments like electrolysis (see [Section 4.43.4.4](#)).

#### 4.43.4.3 Removal of Corrosion Products

Stripping techniques may be employed when ethical arguments allow removal of corrosion, such as preparing lightly corroded industrial and historical steels to receive protective coatings. They may also be used to free archaeological objects from corrosion

conglomerates provided substantial amounts of metal remain, as heavily mineralized objects will lose their identity when corrosion is removed.<sup>8,39</sup> While there are several studies looking into the action of stripping agents there is no single definitive comparative assessment that identifies a preferred method for specified alloys. Conservators must evaluate studies or themselves test stripping agents relative to the object they are planning to treat. That stripping is ethically acceptable at all, illustrates how situation ethics dictate conservation procedures.

Traditional acid stripping solutions are aggressive to metal and corrosion products alike and are now largely ignored, except where it is ethical to remove all corrosion products. Copper alloy coins have been separated using complexing agents exhibiting low aggression to metallic copper to remove copper corrosion products. Citric acid is reported as being best in this respect, when compared to alkaline glycerol, alkaline Rochelle salt, sodium hexametaphosphate, and sulfuric acid.<sup>40</sup> Elsewhere alkaline Rochelle salt is reported as being less aggressive than reagents like methanoic acid, alkaline glycerol and alkaline dithionite.<sup>39</sup> Electrochemical assessment of these reagents would help indicate which reagents offer the best removal of corrosion for the least aggression to the parent alloy. Dealloying is a problem. Predictably, metallic lead is lost from copper alloys by alkaline stripping systems and organic acids. Stripping corrosion from copper alloys<sup>38</sup> and iron<sup>41</sup> has been achieved using thiourea ( $\text{SC}(\text{NH}_2)_2$ ) inhibited citric acid washes. Thiourea controls the aggressive action of citric acid by complexing unstable  $\text{Cu}(\text{I})$  species, to prevent them forming metallic copper, and by forming stable complexes with  $\text{Cu}(\text{II})$ .<sup>8,38</sup> Phosphoric acid ( $\text{H}_3\text{PO}_4$ ) has been used for stripping ferrous metals to leave a ferric phosphate protective film, as has hydrochloric acid with hexamine corrosion inhibitor.<sup>41</sup> All stripping methods require post-treatment washes to remove residual chemicals that would continue to corrode metals. This is often followed by application of a protective coating.

Following citric acid/thiourea treatment of copper alloys, washing in sodium sesquicarbonate is used to neutralize acid and remove  $\text{CuCl}$  left in crevices and cracks, but this is likely to be incomplete.<sup>38</sup> Washing marine copper alloys revealed the benign nature of this treatment method, as tin, zinc, and lead compounds were not removed from either the corrosion products or copper alloy, whereas washing in deionized water removes metallic lead as the purity of the water prevents formation of protective  $\text{PbCO}_3$ .<sup>38</sup> Washing of iron in inhibited chromate or nitrite

solutions following citric acid/thiourea stripping is not environment-friendly, so ecologically superior alkali metal salts of organic carboxylic acids (secacic acid –  $\text{NaOOC}[\text{CH}_2]_8\text{COONa}$ ) have been used to provide washes of similar efficiency.<sup>41</sup> They can also provide long-term inhibitive properties (see [Section 4.43.6.3](#)) and offer promise for widespread use in conservation following more in-depth testing.

Chelating and sequestering agents, such as the sodium salts of ethylenediaminetetraacetic acid (EDTA), have been used extensively in conservation in attempts to dissolve corrosion products without attacking metal. However, they can be slow to act and may be too selective in their action on corrosion products. Careful selection of commercial products is essential to obtain suitable pH values for optimizing complexation. A study examining reaction of disodium edetate ( $2\text{NaEDTA}$ ) on copper corrosion products and copper metal revealed that chelation rate varied according to corrosion product.<sup>42</sup> This would result in differential removal of corrosion products leaving exposed copper open to the treatment solution. Fortunately, metallic copper was barely attacked by  $2\text{NaEDTA}$  over a 30-h period.<sup>42</sup> Dissolved sodium salts of EDTA have also been frequently used to remove corrosion from iron and lead and its alloys.<sup>6,8,31,43</sup> Using compresses allows stripping agents to be used in a controlled manner. Degriigny<sup>44</sup> treated a Citroen caterpillar tracked vehicle used on the trans-Sahara crossing of 1922/23 by this method. It still retained much of its original paint layer. Corroded areas that had sustained paint loss were treated with compresses of tetrasodium edetate ( $4\text{NaEDTA}$ ) to remove iron corrosion products. This was followed by application of inhibitor (see [Section 4.43.6.2](#)) and a protective wax coating (see [Section 4.43.5.4.2](#)) to provide a typical stripping-inhibition-coating treatment regime. All treatment methods were assessed using electrochemical measurements prior to their use. Treatment success was gauged in the usual qualitative manner of visually checking for corrosion as a function of time and no corrosion was visible after 6 months of indoor display. Developing standards for assessing time weighted visual success of treatments set against conservation criteria would produce a useful tool for conservation practice.

Removal of corrosion from copper alloys may also be achieved by alkaline dithionite ( $\text{Na}_2\text{S}_2\text{O}_4$ ) solutions, which provide electrons to reduce corrosion products to finely divided metallic copper.<sup>8,38</sup> Weak heavily corroded objects may be consolidated by this conversion, but there is also a chance they will

disintegrate. The skill and knowledge of the conservator are essential as treatment is fast, lasting only a few minutes followed by a wash of several days to remove residual chemicals.<sup>8</sup>

#### 4.43.4.4 Electrolytic Techniques

Electrolysis is employed in conservation either to entirely remove corrosion products from a metal or to aid diffusion of soluble corrosion accelerating ions into an electrolyte, while retaining corrosion layers on the metal. These differing outcomes are achieved by careful control of current density (CD) and in some instances current delivery. The metal is immersed in a suitable electrolyte and made cathodic relative to an inert anode, which protects it from corrosion during electrolysis. Different metals are electrolyzed in differing ways according to the nature of their corrosion products and the treatment goal. It is an extremely useful technique provided its use matches ethical goals and research identifies optimum treatment methodology. Its context within conservation has only been quantitatively established over the past 15 years since the application of potentiometric electrochemical analysis within conservation research.

Procedures vary from metal to metal. Iron is immersed in an electrolyte in which it will remain passive, such as NaOH. Using an imposed current to cathodically protect the iron frees chloride from its counter ion role, allowing it to solvate and diffuse out of the object.<sup>8,12,29</sup> Chloride is drawn to the inert anode and delocalized from the object by diffusion. Maintaining a low CD retains the information rich DPL by avoiding polarization that would produce hydrogen gas which physically dislodged corrosion layers. Reduction of  $\text{FeOOH}$  corrosion products to  $\text{Fe}_3\text{O}_4$  can occur and the accompanying increase in density increases porosity which is said to contribute to facilitating diffusion of chloride out of the object.<sup>7,8</sup>

Most quantitative assessment of chloride removal by electrolysis has been carried out on cast iron, whose even corrosion matrix is different to the lamellar structure of corroded wrought iron.<sup>2,8,29</sup> Tests on small cast iron chloride infested samples reveal significant migration of chloride to the anode during electrolysis.<sup>29</sup> Quantitative measurement has shown that electrolysis ( $\text{CD } 10 \text{ mA dm}^{-3}$ ) in NaOH solution is no better at extracting chloride than aqueous washing in NaOH solution.<sup>12</sup> While washing is easier to carry out than electrolysis, full inhibition of iron corrosion in a 1% NaOH wash solution cannot be

guaranteed in the same way as an imposed current protects during electrolysis.

Electrolytic treatments are often favored for large iron objects, as they will remain cathodically protected during the long treatment times required to remove deep-seated chloride. Treatment may take from 1 to 4 years for large cast iron cannon and wrought iron anchors from marine contexts<sup>45</sup> and even very small cast iron samples required over 200 days to desalinate.<sup>12,29</sup> As with most metal treatments, there is no report of any quantitative long-term assessment of post-treatment stability of electrolyzed iron as a function of relative humidity. Intentionally using a high CD to remove all corrosion layers may be ethical for certain industrial and historical objects, provided their corrosion layers contain no information and they retain substantial metal cores. Such treatment would usually be a precursor for the application of protective coatings (see [Section 4.43.5](#)).

An advantage of electrolytic treatments is their degree of control, as the imposed potential can be matched to specific reduction processes. They are also useful for large objects, as electrolytic treatments can be run for long periods of time with little input from the conservator thereby saving labor. Circumstance must dictate whether electrolysis is possible. *HMS Minerva* was a big gun monitor launched in 1915 and sold as a visitor attraction in 1984. Removal of the high levels of chloride inside her hull was achieved by flooding it with  $\text{Na}_2\text{CO}_3$  electrolyte and making it cathodic ( $35 \text{ mA m}^{-2}$ ) relative to stainless steel mesh anodes placed directly above it.<sup>31</sup>

Electrolysis can be used to remove all corrosion from lightly corroded lead to reveal fine details on the metal surface. This is normally carried out in sulfuric acid electrolyte. A brief reversal of the electrode poles upon completing treatment makes the lead anodic and forms an invisible  $\text{PbSO}_4$  coating that has protective properties in the atmosphere.<sup>43,46</sup> The final 'fresh metal' appearance of lead treated in this way would influence any decision to use this method. Electrolysis of copper alloys to remove potentially reactive  $\text{CuCl}$  and all other corrosion products is now considered to be aggressive and difficult to control, with a high risk of redepositing reduced copper. Simple electrolysis of copper alloys in water is advocated as deserving of more research, as it can retain the copper corrosion product patina and offer cathodic protection of the metal during treatment.<sup>6</sup>

The inherent insolubility of the silver corrosion products  $\text{Ag}_2\text{S}$  and  $\text{AgCl}$  prevents the formation of electrolytes on corroded silver exposed to high relative humidity. Consequently their removal is largely an

aesthetic act or an information revealing strategy, according to whether the layer is a thin  $\text{Ag}_2\text{S}$  tarnish or a thicker layer of  $\text{AgCl}/\text{Ag}_2\text{S}$  that might be found on archaeological silver objects. Once silver is returned to a shiny metal finish the challenge is to apply coatings or control environments to prevent sulfur-based pollutants tarnishing it (see [Section 4.43.5](#)). Electrolysis removes silver corrosion products within a wide range of operating parameters using electrolytes such as formic acid (5–30%, w/w) or  $\text{NaOH}$  (5–15%, w/w) with CD of  $0.3\text{--}20 \text{ mA cm}^{-2}$  at 3–12 V.<sup>6,13</sup>

Very low current densities have been used to slowly reduce corrosion on mineralized brittle silver objects to metallic silver, which is retained *in situ* to produce a consolidative effect.<sup>13</sup> Conflicting reports of success make this a high-risk strategy, as weak mineralized silver objects may fall apart during treatment due to reduced coherence of their corrosion layers. Potentiometers have been employed to apply potentiostatic cleaning of silver.<sup>13</sup> This method uses a third reference electrode to control the potential of the cathode and a polarization plot is used to identify reduction potentials of the corrosion products, which are then reduced by setting the object potential to match the reduction potential of the corrosion product. It is a finely controlled system that avoids any unwanted reactions such as hydrogen reduction and is useful for tarnish ( $\text{Ag}_2\text{S}$ ) removal.

Once corrosion begins on aluminum and its alloys they corrode rapidly in the atmosphere. Electrolysis can be used to remove chloride corrosion accelerators and unstable corrosion products. Degriigny<sup>47</sup> developed a treatment that cathodically polarized aluminum to constant potential in a buffered deaerated slightly acid citrate solution, with treatment parameters optimized to avoid pitting corrosion from the chlorides extracted into the treatment solution and cathodic corrosion of the metal. Composite aluminum objects associated with other metals like iron are problematic, as significant galvanic couples can be established during treatment. For this type of composite metal object electrolysis is modified. Active polarization of the composite object in an inhibited solution protecting the aluminum alloy from corrosion produces a potential that facilitates formation of a protective magnetite coating on the iron fittings.<sup>48</sup> This is followed by polarization of the object in citric acid solution (pH 7) to remove aluminum corrosion products and chloride. Finally, polarization in deionized water washes out chemicals introduced during treatment. The object is dried and coated with a suitable protective coating (see [Section 4.43.5.4.2](#)).

**Figure 10** Electrolysis of Japanese 'Oscar' aircraft (a) and completed fuselage (b).<sup>49</sup> Image courtesy of Australian War Museum.

Treatments are often fine tuned to the needs of an object. Adaptation of electrolyzing aluminum omitted the magnetite forming step to treat a WWII Japanese Oscar Ki43II fighter retrieved from a saline swamp.<sup>49</sup> The design utilized a swimming pool, 55 000 l of water and 800 kg of chemicals with expanded stainless steel mesh anodes conformed to the shape of the aircraft and sited 30 cm above its surface (see [Figure 10](#)). The inevitable post-treatment flash rusting of ferrous components was dealt with by a tannic acid inhibitor. Original paint and penciled notes on the cockpit fascia were masked prior to treatment. Success was assessed by ongoing observation, as opposed to quantifiable measurements of change or residual chloride in objects.

Imposed currents are used industrially to protect large homogenous steel structures, but heterogeneity and corrosion in historical metal objects produce discontinuities that limit applications of this method for corrosion control. The American Civil War submarine CSS Hunley was recovered in 2000 and stored in a holding tank containing chilled (10 °C) filtered water (see [Figure 11](#)).<sup>50</sup> Storage involves the hull being protected by an impressed current monitored by five electrodes, with two large anode segments running the length of the tank. Comparing corrosion rates of an unprotected mild steel test probe with a similar probe with an imposed current indicated that the post-excavation corrosion rate had been reduced by a factor of 8 and now matched pre-disturbance corrosion rates recorded on the seabed.<sup>50</sup> Protection of the hull by sacrificial anodes was rejected as a preservation option, as it would have required 50 cumbersome 20 kg anodes to be attached to the hull.<sup>50</sup> Impressed current was used to reduce corrosion of the

USS Monitor's steel structure from  $254 \mu\text{m year}^{-1}$  to as little as  $25 \mu\text{m year}^{-1}$ .<sup>51</sup> Measuring the *in situ* corrosion rates of ship and aircraft wrecks to identify the role of galvanic couplings, concretions, coatings, and environment on their longevity has been extensively studied by MacLeod<sup>52</sup> to develop predictive corrosion control strategies in marine contexts.

#### 4.43.4.5 Hydrogen Reduction

Removal of chloride from iron using hydrogen reduction at temperatures of over 800 °C was once seen as a way forward for large chloride contaminated marine objects but is now rarely used. The treatment uses a hydrogen/nitrogen gas mix to reduce chloride bearing compounds at around 350 °C, iron oxides above 570 °C and fully volatilizes iron chlorides and any NaCl present on marine iron at 800 °C.<sup>8,30</sup> High capital outlay, stringent safety measures designed to prevent oxyhydrogen explosions and ethical concerns that changes to metallographic structure compromise technological data and object history limit its use. It may be argued that it is still a viable treatment for cast iron cannon from marine contexts, where technology is well reported and where objects may be considered to be effectively untreatable in any other way due to the amount of deep-seated chloride within them. The technique is reported to provide good post-treatment stability, but suggestion that the method can offer stabilization by reducing corrosion product to metallic iron is challenged by the instability of the reactive pyrophoric iron it produces.<sup>53</sup> Another heat assisted expensive reduction process used in conservation is gas plasma. It has been used

**Figure 11** The H.L. Hunley submarine was lifted from the seabed in a metal frame (a) that was then stored in a large holding tank (b) protected by an impressed current (c).<sup>50</sup> Images courtesy Friends of the Hunley.

to aid chloride removal from iron by reducing  $\text{FeOOH}$  to denser  $\text{Fe}_3\text{O}_4$  to produce a more porous corrosion product layer that aids removal of chloride in subsequent aqueous alkaline treatments.<sup>54</sup>

## 4.43.5 Coatings

### 4.43.5.1 Coating Rationale and Research

Conservation coatings are normally applied as barriers to combat ingress of gaseous, aqueous, or particulate agencies of decay. They may be treatments in their own right or form part of a treatment regime, such as when they are applied as moisture barriers following attempts to remove chloride from iron using washing treatments. Coatings applied to silver must have good gas barrier properties to reduce ingress of  $\text{H}_2\text{S}$  and thereby prevent tarnish.<sup>13</sup> Resistance to vapors such as volatile carbonyl pollutants is important for lead, copper alloys, zinc, and aluminum.<sup>15,18,43</sup>

The role of a coating, environment in which it must be effective and the nature of the metal surface dictate coating choice. An absence of standardized procedures for testing coating effectiveness on cultural metals hinders the use of published material for comparatively identifying the most suitable coating for use in a specific context. While some popular coatings still mostly have qualitative data to support their use, there exists a considerable amount of useful information within conservation literature and there is a move toward providing quantitative data and standardized testing.<sup>3</sup> Both qualitative and quantitative assessment of coating performance within conservation now employs electrochemistry and modern methods of instrumentation in conjunction with increased collaboration with corrosion scientists.<sup>2-4,55</sup>

The concept of manufacturing conservation specific coatings is largely a redundant approach, since conservation viability is cultural rather than commercial as there is no significant financial gain for potential manufacturers in such a small market. Increasing collaboration with industrial partners would benefit conservation and reveal its links to industrial applications. Both industry and conservation seek low toxicity, easy application, predictive performance, and low cost for their coatings. Additionally conservation has stringent ethical guidelines that require coatings to have enhanced life span, long-term reversibility and minimal visible impact to the object upon application or ageing. Object context may modify these goals to some extent. Coatings that offer good protection from corrosion, but are aesthetically displeasing, may be acceptable for objects in long-term storage provided they are easy to remove for display purposes. Since the conservation ideal is for indefinite preservation coatings should be long lasting and low maintenance during their lifespan. Demand for long-term durability and guaranteed reversibility

remain at odds with coating design. While cross-linking polyurethanes have renowned barrier properties their irreversibility, without significant mechanical action coupled with aggressive solvents, rules them out for most conservation applications. Since minimal intervention with an object is contravened by applying a coating and by its future removal, its application is only ethical provided there is evidence that it significantly improves corrosion protection.

Conservation coatings must often perform well on porous, uneven oxidized metal surfaces that may be fragile and chemically unstable. No coating is perfect and this type of surface will result in a large number of coating imperfections. This complicates the testing of coatings for conservation applications, as producing test samples with suitably corroded surfaces to match corrosion patinas developed over years or centuries in the ground or air may be impossible. The alternative of using original materials suffers from reproducibility problems and may be subject to ethical constraints. In some instances actual objects are used to test products. The baton from the bronze equestrian statue of the famous fifteenth century mercenary Bartolomeo Colleoni (see [Figure 12](#)), which is sited opposite the Ospedale San Marco in Venice, was used to compare the performance of organo-silane coatings (see [Section 4.43.5.4.4](#)), synthetic waxes (see [Section 4.43.5.4.2](#)) and acrylic (see [Section 4.43.5.4.1](#)) coatings in tandem with tests on naturally aged metal samples.<sup>56</sup> This approach links the intrinsic properties of coatings to real-life applications and contexts. Samples are not reproducible but performance can be linked to tests on prepared and reproducible samples. Two-phase test systems, where materials are laboratory tested on reproducible samples by accelerated and natural ageing, then tested on objects in real life environments were employed in the PROMET project.<sup>3</sup> This system should be applied to generate evidence-based advice for practical conservators regarding contextual use of materials.

Coatings on metals are used extensively within conservation, but the absence of industry standards makes it difficult to identify the best coating for defined contexts. Much published work produces useful standalone data. This usually compares groups of coatings using highly specific goals and personalized test regimes to deal with the multiple numbers of variables within the test procedures. The demands and complexity of coating use in metals conservation means that many studies naturally attempt to review many aspects of a chosen group of coatings. A stepped study that examines and compares the performance of coatings in relation to a single variable then moves onto the

**Figure 12** The baton from the right hand of the fifteenth century statue of the condottieri Bartolomeo Colleoni in Venice was used for trialing protective coatings. Reproduced from Joseph, E.; Letardi, P.; Mazzeo, R.; Prati, S.; Vandini, M. In *Metal 07, Book 5, Protection of Metal Artefacts*, Interim Meeting of the ICOM-CC Metal WG Amsterdam, 17–21 September 2007; Degriigny, C., Van Langh, R., Joosten, I., Ankersmit, B., Eds.; Rijksmuseum: Amsterdam, 2007.

next would gradually build into a detailed review of materials. Unfortunately, this approach demands significant time and resource commitment and would necessarily be a team project requiring long-term major coordination. Conservation research is not lavishly funded. Collaborative research projects are currently underway or recently completed.<sup>2,3</sup> Their work could offer platforms for movement towards industry recognized standards for testing. Significant coordination and standardization were evident in the recent EU 6th Framework PROMET project.<sup>3</sup> It sought to identify suitable coatings for use on metals within museums surrounding the Mediterranean basin and aimed to identify a methodology for developing and testing inhibitors and coatings for use on iron and copper alloys in museum environments. Additionally it was looking towards environment friendly inhibitor systems.

Many researchers modify international standards or use them unchanged for testing materials and designing experiments. Overall, there remains a

need for developing test procedures that support conservation goals and facilitate comparative performance testing of coating materials for use in conservation. A conservation-specific accelerated corrosion test standard could be used to model the demands of conservation practice. Coating performance in its operational environment is of crucial importance, as it determines its maintenance requirements and life-span. Although laboratory studies, instrumental analysis and electrochemistry can establish intrinsic performance characteristics of coatings according to a set of fixed variables, they cannot offer quantitative assessment of real-time *in situ* performance within museum stores, display cases and outdoor environments. Laboratory testing is useful for establishing which coatings are unsuitable for use and for comparative performance testing in specified conditions. Coatings identified as good performers within the laboratory may fail in the field because certain parameters could not be effectively replicated in the laboratory. However, appropriately designed accelerated ageing normally offers an indication of the relative performance of materials.

Within testing processes examining coating performance a recurring theme is that application methods often dictate whether a coating performs well or badly. The procedure here may be critical. Inappropriate coating methods may negate differences between coatings. A coating with intrinsically better barrier properties may fail at the same rate as one that offers poorer barrier properties because of application methods. Standardizing application methods to ensure variable control is an appropriate experimental procedure, but it may not reflect how the coating will perform in practice where the condition of the object, surface morphology and positioning can dictate whether application is by spray, brush, or cloth. How coatings perform as a function of their application method is as important as their intrinsic properties and should form a major part of testing. A coating with only mediocre barrier properties may perform well if its physical properties suit a particular application procedure. Spraying is often a favored coating method, but coatings of the cellulose nitrate lacquer Frigiline™ on silver were found to fail unevenly due to thickness variations and discontinuities that resulted from spraying.<sup>57</sup> Brushing is known to offer preferential failure in troughs created by the brush stroke and solid wax coatings may have to be applied as polishes. The nature of the surface of the object may also favor different methods of application and mobile self-healing films may be essential in certain environments. The coating itself may dictate which application methods are

possible to use. This overall complex equation must be effectively worked into research studies if results are to be of maximum practical use.

#### 4.43.5.2 Metal Surfaces and Patinas

A major hurdle to the successful application of coatings within conservation is surface preparation. Only in specific circumstances is it ethical to remove patinas and corrosion from surfaces. Within museums equipped with dedicated micro- or macroenvironmental control and monitoring, bare metal surfaces on historical metals may be left uncoated. However, without environmental controls silver tarnishes rapidly in the presence of very low concentrations of sulfur pollutants like H<sub>2</sub>S and forms Ag<sub>2</sub>S<sup>8,10,13,57</sup> and lead and copper alloys are attacked by low concentrations of organic acids.<sup>2,6,8,10,15,18,19,47</sup> Preventive conservation is the preferred option to control pollutant availability and attack, but coatings offer an alternative strategy where sources of pollution cannot be eliminated. Potential for disaster exists in mixed displays or with composite objects, such as when an unstable cellulose acetate object emits acetic acid into an enclosed showcase it shares with a lead object.

Patinas on many metals offer an information resource and provide aesthetic attraction. They may be deliberately applied or naturally formed corrosion layers. Deliberately patinated or polished copper alloy statuary is often modified by corrosion from pollution, rain, and particulates that form corrosion products that may undermine, obscure, or destroy the original patina and outermost metal surfaces<sup>6,19</sup> (see Figure 12). The extent of corrosion will relate to metal composition, climate, location, preexisting patina and the solubility, morphology, uniformity, and adherence of new corrosion products.<sup>6,10,19</sup> Run marks, differential corrosion from pitting, differing colors and textures produced by climate, pollution, composition, and object morphology can entirely ruin object aesthetics and offer a porous uneven surface that will not accept a continuous coating. Wear marks on patinas can be important to retain as part of the history or present life of an object (see Figure 13). Whether total or partial removal of patina is appropriate, in return for improved object stability and surface preparation for coating, presents ethical and aesthetic dilemmas for the conservator.

Apart from ethical considerations, establishing the role of a patina in the corrosion process can help decide whether to remove it as part of a corrosion control strategy. Equally an understanding of patina stability

**Figure 13** Constant touching of this copper alloy hand has created a wear mark patina that now forms part of the object history and presents a dilemma for conservation planning (a). Achieving a continuous coating on archaeological copper alloys is problematic due local corrosion and differential patina (b).

and protectiveness contributes to developing corrosion control strategy by offering a measuring point for monitoring, assessing, and predicting patina deterioration with time.<sup>58</sup> Nondestructive *in situ* analysis has been used to identify variance of electrochemical stability within patinas to locate areas that offered high stable electrode potential relative to the base metal, as they provide good corrosion protection.<sup>59</sup> Results revealed that unsightly black crusts offered more protection than visually acceptable blue/green corrosion product layers. This creates an aesthetic dilemma for conservation strategies based on patina retention. Understanding the contribution of corrosion layers to the corrosion process makes it easier to determine if interventive treatments are a better corrosion control option than noninterventive monitoring strategies.

Disfiguring, unstable and aesthetically displeasing patinas formed by corrosion may be removed, either

to reveal metal or a selected corrosion product layer in preparation for repatination and/or adding a protective coating.<sup>6</sup> Repatination may even form part of a corrosion control strategy, as some patinas may offer a degree of protection by acting as partial barriers to moisture, electrical conduction, and gases.<sup>6</sup> Instrumental analysis and historical research to determine the original appearance of a metal object is a prerequisite to selecting a repatination process. Working objects and industrial equipment that never developed a patina or were frequently repainted may in some instances be stripped to the metal surface, provided their history is not compromised by loss of data such as paint layer sequences. Analysis of paint layers would determine if this was likely to occur. Stripping processes like electrolysis, chemical dissolution and complexation, which remove corrosion prior to applying coatings, should provide for lower maintenance of coatings, all other factors being equal. Yet there remain ethical dilemmas concerning the stripping of historical metals.<sup>60</sup> During its working life a cog may have uncorroded teeth that developed a surface finish from work, with a corrosion patina on its ‘noncontact’ body that can also be associated with its working life; should conservation retain both these layers?

#### 4.43.5.3 Preparing Surfaces on Cultural Objects to Receive Coatings

Surface preparation of objects may take the form of mechanically removing disfiguring corrosion to reveal the ‘original’ surface of the object or the marker layer for this. In archaeology it is normal to use mechanical systems to remove corrosion to reveal the object shape and surface detail.<sup>7</sup> For historical metals preparation may involve mechanical cleaning systems, chemicals, or electrolysis. Precious metals may be polished to a high shine as the goal of coating is to ensure that future repolishing occurs as infrequently as possible. In all cases it is best to remove soluble corrosion accelerators before applying coatings.

Outdoor statuary is cleaned according to the goals of the conservation process, taking account of ethics and aesthetics. Preparing surfaces by stripping patinas is normally unacceptable due to ethical constraints and aesthetic outcomes (see [Figure 14](#)). All processes must involve minimum loss of material. Choosing a cleaning method normally relates to how it physically modifies surfaces and alters appearance, rather than its impact on metal stability by removing corrosion accelerators or making a surface more coating friendly, unless it is being prepared for paint. Cleaning methods

**Figure 14** This contrast between a surface retaining its uncleaned patina and a section cleaned by airbrasion with aluminum oxide starkly reveals the tension between best practice for preparing surfaces to receive coatings and the aesthetic and ethical constructs of conservation.

will influence the effectiveness of coatings, as leaving corrosion products and patinas *in situ* influences their adhesion and distribution.

Most studies qualitatively compare the effects of cleaning methods on specific metal surfaces. Dry particulate abrasion, pressurized water and chemicals have variously been compared for cleaning patinated copper.<sup>61</sup> One study serves to illustrate some of the decision making associated with cleaning surfaces. It compared cleaning of a patinated copper alloy token by abrasion techniques employing glass beads, walnut shell, corn cobs, and sodium bicarbonate delivered at pressures between  $1.38 \times 10^5$  and  $5.52 \times 10^5$  Pa with simple abrasion using  $\text{Al}_2\text{O}_3$ , pressurized water and chemical cleaning by complexation (solution comprising KNaTartarate, 2NaEDTA, NaOH, and fumed silica applied in a cellulose ether gel pack).<sup>61</sup> Postcleaning samples were exposed to synthetic rain and their corrosion was monitored.

Results of these tests reveal the general dilemma produced when trying to balance effectiveness with aesthetics and ethics. Although chemical cleaning offered the most stable substrate, as observed after 1 year, it produced the most visually altered surface by removing all overlying green corrosion products to leave only orange/brown  $\text{Cu}_2\text{O}$  *in situ*. Predictably the softest corrosion products disappeared from the mechanically abraded objects, which were less stable than the chemically treated sections. Pressurized water produced the least visual change, but removed the most soluble corrosion products leaving the metal actively corroding after a year. None of the methods entirely stabilized the metal and various corrosion

products were left *in situ*, neither did they remove all corrosion accelerators. Other workers have expressed concern at indiscriminate surface preparations that fail to recognize the importance of original coatings on metals like aluminum.<sup>16</sup> Glass beads have been cited as being too damaging on finishes on aluminum alloys, but airbrasion can be retained by use of plastic beads at  $1.0 \times 10^5$  Pa.<sup>16</sup>

Preparing historical metals and objects d'art that traditionally carry a shine for the application of coatings involves either chemical or physical removal of tarnish. Removing  $\text{H}_2\text{S}$  tarnish from silver can be achieved by chemicals or abrasion.<sup>13</sup> Chemicals are aggressive and may lead to differential corrosion and surface enrichment of alloys such that loss of copper alloyed with silver leaves a soft and porous silver enriched surface. They may also leave residues that are too aggressive and these have been tested to determine their impact on the object and develop a protocol for treatment. Polishes remove metal and produce surface scratching. Studies of polishing methods concentrate on the loss of metal incurred and scratching of the surface, with  $\text{CaCO}_3$  being a favored inert polish for silver.<sup>62</sup> Chemicals are normally only preferred for heavy tarnish due to the risks of preferential leaching of alloying components and the need for acidified complexing agents to remove  $\text{Ag}_2\text{S}$ .<sup>12</sup> Potentiometric methods mentioned earlier can also be used to remove silver tarnish (see Section 4.43.4.4). Focus should be on identifying the least interventive method that offers the best surface for receiving a coating.

#### 4.43.5.4 Coatings in Conservation Practice

There are a small range of generic coatings in general use within conservation and there is no definitive comparative study which clearly identifies the most successful coating for any given context. Preferences and trends exist for various chemical groupings and products.<sup>3</sup> Coatings are reviewed below by chemical affiliation, rather than their application to specific metals. Trade names are used in general discussion, having initially defined the chemistry of the product.

##### 4.43.5.4.1 Acrylic coatings

The Paraloid™ range of acrylics, known as Acryloid™ in USA, is commonly used within conservation practice. Other acrylics are used according to availability, which means geography can dictate choice of materials. Survey reveals that only a few coatings are routinely used, with Paraloid B72™ (70 methyl methacrylate/30 ethyl acrylate copolymer) being one of the most popular general purpose surface coatings

for cultural metals. Its long-term reversibility and application as a coating, consolidant, and adhesive make it a workhorse within conservation and a comparative performance standard in many test procedures.<sup>3</sup> Performance of Paraloid B72™ and an ethylene based commercial coating Poligen ES 91009™ were compared, both alone and with added inhibitor as coatings on fresh and precorroded coupons of steel exposed to cycling  $\gamma$  (90% at 35 °C to 55% at 25 °C) to simulate extreme museum environmental fluctuations.<sup>3</sup> Performance was assessed qualitatively by visual interpretation and quantitatively using EIS and polarization techniques.<sup>3,63</sup> Poligen ES 91009™ was more effective than Paraloid™, and added inhibitors failed to significantly improve the performance of either coating. Long-term exposure of similar test coupons in museum environments confirmed that although Paraloid B72™ gave ‘quite satisfactory results,’ it failed at edges producing filiform corrosion.<sup>3</sup> This was recognized as being problematic where much cultural material like edged weapons and armor had multiple thin edge sections. The importance of environment was revealed in these tests as matched sample sets performed differently over similar exposure times within museums in differing Mediterranean countries. Application method was again revealed as being an important variable. In one test, a 250  $\mu\text{m}$  layer of polyurethane (Rylard™ boat varnish) performed much better than either Paraloid B72™ (40  $\mu\text{m}$ ) or an innovative physical vapor deposition system (<1  $\mu\text{m}$ ).<sup>3</sup> Standardizing test methodology by employing aged coupons and using laboratory and onsite real-time testing in monitored environments offers a solid test platform for cultural metals and for the evolution of assessment standards. Yet outcomes discounted certain products due to outright failure, it proved difficult to quantify the performance of some of the more successful coatings. Overall, the study revealed weaknesses in the performance of traditional conservation materials and identified the newly tested Poligen ES 91009™ as offering promise for the future.

The inability to separate lead organ pipes from oak supporting frames emitting organic acids in European Baroque organs led to a research program that tested the ability of coatings and inhibitors to prevent the corrosion of lead by organic acids.<sup>64,65</sup> Using an aqueous washing strategy to remove soluble lead methanoates and ethanoates acting as electrolytes failed to reduce the corrosion rate upon reexposure of the lead to the methanoic (170 ppb  $\text{Pb}(\text{CHOO})_2$ ) and ethanoic acid (195 ppb  $\text{Pb}(\text{CH}_3\text{COO})_2$ ).<sup>65</sup> Coatings alone produced limited protection, with Paraloid B72™ offering no protection, microcrystalline wax providing uneven

protection and various inhibitors had little effect.<sup>64,65</sup> This is of concern as Paraloid B72™ has long been used as a coating on lead. Treatment must be effective for the long term, due to the cost and logistics of coating the organ pipes. Nanotechnology is now being tested in a preventive treatment using  $\text{Ca}(\text{OH})_2$  nanoparticles to control acid emission from the wood.<sup>64</sup>

Incralac™ lacquer comprises Paraloid B44™ (ethyl methacrylate/butyl acrylate copolymer) with added epoxidised soya bean oil as a leveling agent and benzotriazole as a UV absorber<sup>6</sup> and is industry designed for protecting copper alloys. It has been extensively used both on archaeological and outdoor copper alloys since the 1960s. Its application aesthetically changes bronzes by darkening their surface.<sup>56</sup> However, outdoor exposure is likely to result in optical changes to most coatings as they weather and collect dirt. Good electrochemical impedance measurements recorded for fresh Incralac™ coatings on polished and unpolished bronze, implied good coverage and low porosity, but after natural ageing on a rooftop in Canberra for 4 years impedance was the same as for uncoated metal.<sup>57</sup> Although two coats improved performance the time-related failure remained the same. Poor long-term performance was also found in 10-year-old Incralac™ coating on a gilt bronze statue in New York.<sup>6</sup> It was entirely cracked and its insolubility was likely due to cross linking exacerbated by the loss of the BTA UV stabilizer which was absent in the aged lacquer, which required strong solvents and physical intervention to reverse it. Inhibitors such as benzotriazole (see [Section 4.43.6.1](#)) have been used to prime bronze surfaces prior to applying Incralac™.<sup>6</sup> The manufacturer reports a 5-year lifespan with removal instructions recognizing its reduced solubility with age, but a 2-year lifespan on outdoor copper alloy monuments is more common. The outdoor performance of Incralac™ is limited when measured against conservation goals of low maintenance, good protection, and reversibility but it continues to be used in the absence of any quantitative proof of significantly better performing alternatives.<sup>6</sup> Survey suggests Incralac™ is now less commonly used on historical and archaeological metals inside museums, apparently in favor of Paraloid B72™.<sup>3</sup>

Solvent-based acrylic resins and their aqueous dispersions have been tested as  $\text{H}_2\text{S}$  barriers in a program comparing them to vinyl acetates, cellulose nitrate and microcrystalline wax.<sup>66</sup> Acrylic dispersion systems performed better than the acrylic resin solutions and were equal performers with vinyl acetate and cellulose nitrate, but the defining factor in protectiveness of all

the coatings tested was their evenness and thickness. Uneven coatings produced differential tarnishing. Microcrystalline wax (Renaissance Wax™) produced the worst result because its solid state made it difficult to apply. The conflict between good experimental procedure and practical use of coatings is reflected by drying coatings for 8 months prior to testing them with H<sub>2</sub>S, as this is unlikely to reflect the procedure within museum contexts.

Fragile metal objects are held together by impregnating them with polymers using immersion systems. Acrylic polymers like Paraloid B72™, microcrystalline waxes and occasionally, epoxy resins are used for fragile iron.<sup>7,36</sup> Unsurprisingly, long-term survey reveals that iron objects washed to remove chloride and then consolidated with epoxy resins survive better than washed iron that remained unconsolidated.<sup>36</sup> Epoxy resin coating offers a degree of protection against moisture ingress and its strength as an adhesive retains the physical integrity of the iron even if it corrodes.<sup>36</sup> While the insolubility of epoxy resins appears to contravene the central conservation concept of reversibility, its use is measured against increased longevity of the iron as a cultural resource. The influence of ethics on treatment choice takes account of both the prevailing situation and the ultimate goal of prolonging the functional life of an object.

In reality even the use of a reversible consolidant is effectively an irreversible process. Since its use implicitly acknowledges it is essential for retaining the physical integrity of an object, overcoming consolidant/metal interactions to remove it would likely result in object fragmentation. While there have been no conservation studies on the influence of epoxy resins on the corrosion of metals, less viscous short chain aliphatic epoxy resins suited to consolidation processes produce more OH groups upon cross-linking than aromatic epoxy oligomers, which means they attract more water from the atmosphere and this may facilitate greater corrosion. Trapping moisture within iron objects by using consolidants and coatings runs the risk of creating microclimates that may accelerate and localize corrosion.

#### 4.43.5.4.2 Waxes

Microcrystalline waxes are commonly used as coatings in conservation, especially on smooth even steel surfaces such as armor<sup>3</sup> and patinated outdoor monuments.<sup>6</sup> Recent  $E_{\text{corr}}$  studies revealed one such wax offered little or no protection when compared to the acrylic Paraloid B72™ and polyethylene wax Poligen ES™ on smooth steel in contact with electrolytes.<sup>3</sup> Interpreting this

failure illustrates the importance of taking account of environment and metal substrate, as when microcrystalline waxes were tested on lead exposed to atmospheres containing organic acid vapor they performed significantly better than Paraloid B72™.<sup>65</sup>

Renaissance™ and Cosmoloid 80H™ waxes are the most commonly cited microcrystalline waxes in conservation literature. Typically in conservation, particular commercial products tend to be preferred for use over long time periods.<sup>3</sup> In what is often a nonevidence-based manner the perception grows that they are ‘proven’ products. Replacing popular coatings that are no longer being manufactured presents a problem. An extensive study was set up to find the best commercially available alternative for a microcrystalline wax being phased out of production. A range of microcrystalline waxes and a low melting point (80–100 °C) polyethylene wax were compared using electrochemical impedance spectroscopy and immersion in 0.1 M NaCl, supported by real-time atmospheric exposure.<sup>55,67</sup> BeSq 2095™ microcrystalline wax performed similarly to TWA 2095™ which was being phased out. Real-time testing was an essential part of this study and identified complete failure of the waxes over a 4-year exposure period. As reported for many other test procedures it was the application method that once again provided a significant influence on performance. BeSq 2095™ microcrystalline wax performed better when applied in a molten state, which produced crystalline lamellae, whereas polyethylene wax offered best protection when buffed onto bronze surfaces.

Protection of bronze ethnographic and artistic objects with waxes provides a transparent coating with a degree of color saturation that meets aesthetic goals. Sticky aesthetically displeasing mobile wax coatings that alter color saturation of surfaces are not used in conservation, unless the object is to be stored. A number of commercial products comprising wax and volatile corrosion inhibitor additive were ranked as better performing coatings for outdoor bronze sculpture, as compared to the conventional microcrystalline wax BeSq 195™ using electrochemical impedance spectroscopy.<sup>67</sup> Dinitrol 4010™ performed best. It is used by the aerospace industry to protect engines in storage.<sup>68</sup> and it is a preferred choice for electrolyzed aluminum alloys,<sup>16,47,68</sup> although a note of caution was expressed on the use of inhibited commercial waxes for aluminum alloys without first examining their relationship with the corrosion processes taking place.<sup>16</sup> A Focke-Wulf 190 aero engine treated by electrolysis was coated with a 40 μm layer of Dinitrol

4010™ post treatment,<sup>68</sup> which has good protective properties and is favored by the aircraft industry because it has no adverse affect on rubber and plastics.

Wax coatings are considered to be high maintenance options for outdoor bronzes, as compared to acrylics. However, they are used as sacrificial topcoats on outdoor bronze statuary where they protect the underlying acrylic layer from degradation. A three-phase system of Benzotriazole inhibitor primer, Incralac™ main coat and microcrystalline wax topcoat has been employed by a number of workers and offers a more robust protective system.<sup>6</sup>

#### 4.43.5.4.3 Cellulose nitrate

Before the introduction of the Paraloid™ range of acrylics, cellulose nitrate was commonly used in conservation as an adhesive and a coating. It has proven long-term reversibility and its properties and decay have been extensively reported. Long-term performance studies discounted its effectiveness as a coating on archaeological iron.<sup>3,34</sup> Although it has been in long-term use as an antitarnish coating on silver the cellulose nitrate lacquer Agateen™ only equaled the performance of acrylic and vinyl acetate emulsions in laboratory tests.<sup>66</sup> As with many other coating studies on silver, tarnishing from sulfur was strongly influenced by coating methods and the quality of their application.<sup>57,66</sup> Anecdotal reporting suggests recoating silver to protect against tarnishing is necessary every 10 years. This is an expensive and time consuming exercise for a large silver collection, so coating lifetime has been explored using accelerated ageing tests.<sup>69</sup> These revealed that light and relative humidity had a pronounced effect on the lifetime of the commonly used cellulose nitrate lacquer Frigilene™. Extrapolating the results of the accelerated tarnishing tests indicated that Frigilene™ should still protect from tarnishing after 10 years in mid-range relative humidity values. Calculations did not account for thermal effects inherent in accelerated ageing tests, so lacquer lifetime was expected to be greater than 10 years' exposure at room temperature.

Appropriately these laboratory tests are being evaluated by English Heritage using real-time monitoring of the Waterloo silver centerpiece in Apsley House, London. In several years' time the final outcome will offer insight into the effectiveness and value of the test procedures, as much as the performance of Frigilene™ lacquer as a gas barrier. Focused pragmatic studies such as this offer tangible evidence for choosing materials fit for task and for devising long-term conservation planning and budgeting. The reported testing

supplied sufficient information for the production of a predictive conservation strategy. Benign impact on metal, proven reversibility, and long operational lifespan are the main essentials for conservation planning, which, in this instance, revealed that cellulose nitrate was a good choice for antitarnish coatings on silver. Although investigations into the surface chemistry relationships between cellulose nitrate and silver would offer insight into mechanisms of protection and failure, it is not necessary in order to devise a preservation strategy.

#### 4.43.5.4.4 Silanes

While organosilicon compounds are extensively used in industry,<sup>70</sup> they have received limited attention in conservation practice. It appears that there is much scope for employing them on cultural metals as hydrophobic barriers, as they are largely invisible on surfaces, are good water repellents and are capable of bonding to corrosion products.<sup>70</sup> Barrier properties of silanes can be improved with the inclusion of inorganic additives like silica plates, which can reduce water permeability and aid reversibility. Eventually silanes will be broken down by water reaching the metal–silane interface, where it reverses the Si–O–Me bond that was formed by hydrolysis to protect the metal. Applying thicker films cannot be used to counter this as they tend to be too brittle and application difficulties are experienced.<sup>70</sup>

Organic–inorganic polymer systems produced by hydrolysis and condensation reactions of alkoxy silanes and organo-functional alkoxy silanes have been tested on bronze, fresh, and precorroded steel in the form of the Ormocer™ (ORganically MODified CERamic) family of lacquers produced by the Fraunhofer Institute in Munich.<sup>71</sup> Good adhesion to metal surfaces and their hydrated corrosion products should occur due to the presence of Si–OH and Si–O–R groups in the polymer and an organic polymeric network results from the cross linkable functional groups of alkoxy compounds (R–Si(OR)<sub>3</sub>). Ormocer™ lacquers can be modified to produce differing elasticity, by reacting their main cross linkable component glycidoxypropyl trimethoxy silane with alkoxy and hydroxy silanes.<sup>71</sup>

These lacquers significantly outperformed waxes in laboratory-based accelerated (SO<sub>2</sub>) corrosion tests and outdoor exposure using various international standards.<sup>72</sup> Application method and concentration proved important to performance. Monolayers (4–8 μm) and bilayers (10–12 μm), applied by spray, darkened metals and the monolayer performed better

than the bilayer on patinated metal. This data indicates that it may be a promising coating for corroded metals, but technical and ethical boundaries must be crossed when using it. Ormocer™ requires methylene chloride paint stripper to reverse it. Testing this lacquer in SO<sub>2</sub> contaminated environments reflects its initial conception for use within industrial contexts, where polluted environments offer significant threat. Despite the siting of many cultural metal objects in urban contexts surprisingly few studies within conservation examine coating performance in SO<sub>2</sub> contaminated conditions.

As in other areas of conservation comparative studies dominate conservation research into silanes. An EU research project (ARCHITECH) seeking to identify better coatings for outdoor art works is examining silane coatings, copper oxalate patinas and increasing the thickness of Cu<sub>2</sub>O layers to improve the natural protectiveness of patina on copper alloys.<sup>56</sup> Comparing selected silanes to the commonly used Incralac™ acrylic coating revealed them to perform only equally well, which is not encouraging given the overall weak outdoor performance of Incralac™ (see Section 4.43.5.4.1). The fact that Incralac™ altered the chroma of the metal surface more than the silanes<sup>56</sup> does not seem to offer strong support for using silanes. The fact that Ormocer™ showed better adhesion than Incralac™ in high humidity<sup>72</sup> may be of use, but such conditions are likely to more readily induce its hydrolysis. The PROMET project included Silane A (5%  $\gamma$ -mercaptopropyltrimethoxysilane; 2%bis-(trimethoxysilylpropyl)amine; 1% hydrated tetraethoxysilane; 92% ethanol) in its comparative testing regime.<sup>3</sup> This offered best protection for bronze in long-term real-time testing, as compared to Paraloid B72™ and selected corrosion inhibitors. However, all systems failed over the test period. There are many difficulties to overcome if silanes are to be successfully used on cultural metals.

#### 4.43.6 Inhibitors in Conservation

Inhibitors are used selectively and, in many cases, empirically in conservation practice, either alone or in combination with coatings. While their use is governed by the usual ethical constraints of appearance and reversibility, fashion also has an input. For instance the blackening of iron by tannate inhibitors may be deemed to be ethically acceptable on archaeological iron, as it could be argued that visual changes

do not stray too far from the appearance of the gray/black DPL layer retained on objects.<sup>2</sup> This encapsulates the flexible nature of ethics and aesthetics within conservation, as the slight darkening of patinas on copper alloys caused by the use of benzotriazole is cited as being of concern by some authors. Whether inhibitor use in conservation can be reconciled with the goal of stabilizing metals is debatable, as inhibitors slow rather than prevent corrosion.

No inhibitors have been specifically developed for use in conservation practice. They are borrowed from industrial contexts, where they have been assessed for use in specific operational environments on particular alloys. As with protective coatings inhibitors are required to be effective in the presence of corrosion products. This presents difficulties, as soluble corrosion accelerators like chloride ions normally interfere with their action. Low inhibitor toxicity is also a requirement, as objects remain in the public domain where they must be accessible and easy to handle. This tends to rule out many vapor phase inhibitors, as these are often based on volatile and toxic amine base compounds. Attempts have been made to find less toxic alternatives and cheap natural inhibitors. Recently extract of seed oil from the cactus *Opuntia ficus indica* was used to formulate an inhibitor that contained long chain fatty acids, triethanolamine, and potassium hydroxide<sup>3</sup> but it failed to offer protection when compared to a range of coatings. This is likely due to poor film formation, as a continuous film reportedly constitutes its inhibitive properties. In the same tests, adding corrosion inhibitors to films failed to improve their protective properties significantly.<sup>3</sup>

##### 4.43.6.1 Benzotriazole (BTA)

1,2,3-Benzotriazole is the most successful commercial inhibitor used in conservation practice. It is applied to prevent corrosion of chloride contaminated copper alloys.<sup>6</sup> There is some discussion whether it is the inhibitive properties of BTA or the barrier properties of Cu–BTA films that infer protection to patinated chloride containing copper alloys. The Cu(I)–BTA inhibitor complex films formed on copper, copper alloys, and Cu<sub>2</sub>O surfaces have excellent adhesion from primary and secondary bonding and likely play the dominant role in the protection of patinated copper alloys by limiting water, ion, and oxygen ingress to reactive metal and mineral surfaces.<sup>2,73,74</sup> The film tolerates chloride ions and low-pH environments and reacts with CuCl to produce a BTA–chloride compound that is stable at high humidity<sup>72</sup> (see

**Figure 15** Benzotriazole was specifically applied in conservation practice to combat 'bronze disease'; the growth of voluminous  $\text{Cu}_2\text{OH}_3\text{Cl}$  polymorphs at the  $\text{Cu}_2\text{O}$ – $\text{CuCl}$  interface beneath shape-retaining overlying corrosion layers. Their loss is visible on this Roman pin.

**Figure 15).** Compared to a range of other nitrogen or sulfur-containing organic compounds it is more effective (99%) at inhibiting hydrolysis of  $\text{CuCl}$  to  $\text{Cu}_2(\text{OH})_3\text{Cl}$  and although both 2-mercapto-benzimidazole (98% effective) and 2-mercapto-benzothiazole (97% effective) approach its inhibitive properties, they form aesthetically unacceptable white and yellow complexes with  $\text{CuCl}$ .<sup>75</sup> The black-green coating BTA produces when it reacts with  $\text{CuCl}$  is probably why BTA is noted for darkening patinas on copper alloys. This is a small trade-off for its proven effectiveness at preventing corrosion.

There is no definitive agreed and tested protocol for its use. It is normally used as a 3% solution in alcohol or 1% in water, with no quantitative evidence to support suggested treatment times that range from paintbrush application through a few hours in vacuum to several days soaking. Archaeological and deeply pitted copper alloys often prove difficult to stabilize using BTA solutions, as hydrolysis within pits creates a low pH that interferes with the formation of an effective  $\text{Cu}$ –BTA coating. This is overcome by pretreatment of pits with  $\text{Na}_2\text{CO}_3$  but at an aesthetic cost of producing brown-colored spots.<sup>6</sup>

Factors influencing copper–BTA reactions and the nature of the resulting film include the condition and oxidation state of the reacting surface, potential, temperature, pH, and chloride and oxygen concentrations. Thus  $\text{Cu(I)}$  complexes formed in acid corrosive environments tend to be thicker, less polymerized, and more permeable to oxygen than equivalent films formed in neutral and deaerated conditions.<sup>73</sup> This diversity in film formation indicates that there would

be considerable benefit in tests designed to examine the nature of the films formed to determine optimum application conditions. For instance, it appears that deoxygenated solutions may offer an advantage over current oxygenated treatment environments and short treatment times could explain why BTA sometimes fails to inhibit corrosion. Tests on artificial patinas have shown that it takes several days for reaction with brochantite ( $\text{Cu}_4\text{SO}_4(\text{OH})_6$ ), which is a common corrosion product on outdoor statuary in urban areas, to go to completion.<sup>38,74</sup> Although the acid by product of this reaction lowers pH as concentrations of BTA increase, a dilemma exists as treatment must ensure there is excess BTA present to repair any damage to the protective BTA polymeric film formed.<sup>74</sup>

Use of BTA on outdoor statuary requires a regular maintenance program, as BTA is likely to be lost from effects of rain-wash due to its solubility and volatilization because of its low vapor pressure. The use of BTA as a primer coated with protective lacquer(s) should prolong its effectiveness. Additionally, BTA also forms  $\text{Pb}$ –BTA and  $\text{PbO}$ –BTA compounds as crystalline polymeric films which have been shown to protect lead within leaded bronzes from corrosion by organic acids<sup>76</sup> and  $\text{Zn(II)}$ –inhibitor complexes have been detected on copper alloy.<sup>2</sup> In contrast electrochemical measurements showed silicon bronzes had lower organic inhibitor efficiency as silica is poorly reactive towards BTA.<sup>2</sup> It is clearly important to know what copper alloy is being treated to assess likely inhibitor effectiveness.

Whether copper alloys routinely require treatment with BTA is questionable. What percentage of objects would have remained stable, even if they had not been treated with BTA, is unknown. Many patinated copper alloys treated by BTA appear stable in museum environments, although this observation remains unsupported by quantitative data. A study of surface chemistry reactions with the typical corrosion profiles found on copper alloy objects and quantitative long-term studies of copper alloy object stability following treatment with BTA would determine its inhibitive powers relative to the conservation goals of longevity and predictive success.

Despite its proven inhibitive success, workers still seek alternatives to BTA mainly due to toxicity worries and its high cost. While no better inhibitor for cultural corroded copper alloys has been recorded, synergistic inhibitive effects have been identified when using BTA with other inhibitors that included 5-amino-2-mercapto-1,3,4-thiadazole.<sup>77</sup> Caution is

required when mixing inhibitors as the formation of differing BTA complexes can lower performance of BTA.<sup>75</sup> Recently BTA with a hydrophobic alkyl side chain (C6-BTA) has been tested on the basis that the side chain will better repel aqueous electrolyte.<sup>2</sup> A more novel use for BTA is as an inhibitive washing procedure for marine iron, where it forms Cu(I) complexes and Cu(II) species and prevents corrosion while the water wash extracts chloride from CuCl.<sup>38</sup> A big advantage of using a BTA preservation strategy on copper alloys is that it can be applied without any surface preparation, which is ideal where patina is part of the intrinsic value of the object. Ensuring access to the Cu<sub>2</sub>O layer that is normally situated next to the metal or integrated with CuCl sited there will provide the best opportunity for treatment success, due to the ability of BTA to react with this oxide. Unfortunately, removing the overlying green brochantite/antlerite/malachite patinas to reveal orange/red Cu<sub>2</sub>O would be visually unacceptable in many instances.

#### 4.43.6.2 Tannins

As conservation seeks to balance its goals with global concerns regarding toxicity and carbon footprints, testing low toxicity inhibitors derived from natural sources like plant extracts is of interest. Tannin plant extracts have been used intermittently in conservation since the 1960s and are reported to act as rust converters, leaving a black inhibitive film on the metal. Treatment involves either immersion in tannin solutions or, more likely, painting onto objects. Currently there is no quantitative in-depth study of their action within conservation contexts or any data that offers quantified guidance for optimum treatment concentrations or application procedures.

It is well known that condensed tannins applied either in water or solvent to rust-covered iron offer inhibitive properties by forming ferric-tannate complexes that act as insoluble barriers and phosphoric acid is said to improve inhibitive properties. Tannate-coated iron performed well in long-term storage according to a qualitative survey of archaeological iron.<sup>30</sup> While this provides useful information, post-treatment stability studies for determining treatment success should be controlled and semiquantitative with clear links to environmental variables, rather than retrospective examinations of treated objects.

Iron stripped by 4NaEDTA was coated with a mixture of phosphoric and tannic acids to inhibit further corrosion, following electrochemical testing to determine optimum concentrations and combinations

of inhibitor.<sup>44</sup> A recent study identifying optimum concentrations of tannin and phosphoric acid for inhibiting corrosion of rusted iron in a 3.5% NaCl solution indicates the importance of research and testing to optimize tannin applications to meet the prevailing circumstances. In this study,  $E_{\text{corr}}$  values showed that phosphoric acid reduced the inhibitive properties of mangrove tannins at low pH (0.5 and 2.0), yet when used alone at higher pH (5.5) it offered improved inhibition as compared to tannin/phosphate mixtures.<sup>78</sup> Corroding archaeological iron has varying pH across its surface due to hydrolysis of anodically produced Fe<sup>2+</sup> and its thick corrosion layers. Any testing of tannins for use in conservation practice should be tailored to the corrosion model extant.

As with other protective surface coatings testing the stability of treated objects at typical storage humidities is necessary and, until this is achieved, application of tannins in conservation will retain a degree of empiricism. To date, no inhibitor has been shown to have effective long-term inhibitive action on chloride-contaminated archaeological iron retaining its corrosion layers and exposed to mid to high relative humidities. Commercial tannate-based inhibitors have been tested and shown to be effective for inhibiting internal corrosion of boilers in the working nineteenth-century paddle steamer PS Enterprise between its weekly use on lake Burley Griffin, Australia<sup>79</sup> (see Figure 16). In these closed systems the boiler retains its water and inhibition results from a combination of reducing the availability of oxygen, formation of iron tannate film and precipitation of dissolved salts as sludge.

#### 4.43.6.3 Carboxylates

Sodium carboxylates (CH<sub>3</sub>(CH<sub>2</sub>)<sub>*n*-2</sub>COONa – usually *n* = C<sub>10</sub> or C<sub>12</sub>) derived from vegetable oils have been used on copper alloys and iron to form inhibitive copper and iron carboxylates.<sup>2,3,41,80-82</sup> Like tannates, they are environmentally friendly. They have been linked to conservation in tests on corroded iron and copper coupons and blank standards.<sup>41,80</sup> Potentiodynamic curves revealed they offered slightly better inhibition than mimosa tannin solutions and considerably better protection than phosphates tested on bare clean steel coupons.<sup>80</sup> A further advantage is that the nanomeric hydrophobic iron carboxylate soap layer formed by reaction with iron cations<sup>79</sup> is not aesthetically disfiguring, as is a black iron tannate layer. Carboxylates readily reverse in ethanol, which may mean they are best suited to indoor applications. Long-term

**Figure 16** Tannates are used to protect the boilers in this 19th-century paddle steamer belonging to the National Museum of Australia. Image courtesy of David Hallam.

real-time testing using precorroded metal coupons indicated that sodium decanoate offers temporary protection on partially oxidized historic steels and may be considered as an alternative to Paraloid B72™.<sup>3</sup> It also offered good protection for copper alloys.

Carboxylates were originally tested in conservation as inhibitors for preventing corrosion of lead by volatile organic acids.<sup>81</sup> Polarization plots produced by modeling corrosion of inhibited lead by these acids indicated that sodium decanoate and undecanoate protected best against corrosion, whereas phosphate inhibitors actually increased corrosion rates.<sup>65</sup> Real-time X-ray diffraction studied the resistance of lead carboxylate ( $\text{CH}_3(\text{CH}_2)_8\text{COO})_2\text{Pb}$ ) films to acetic acid vapor and revealed considerable protective properties, but ultimate failure.<sup>82</sup> Carboxylates appear to delay corrosion by organic acids, but ultimately they cannot prevent it. As in other areas of conservation, contextual needs dictate preservation strategies, while these tests showed carboxylates as being unsuitable for preserving church organs, they may be considered suitable where lead is more accessible and easy to monitor to determine if retreatment is necessary.

#### 4.43.7 Painted Metals

##### 4.43.7.1 Removing Paint

Conservation ethics normally dictate that original or later paintwork that offers either a record of the history

of the object or milestones in its life should be preserved. The preservation of fragmentary original paint surfaces is challenging, as pitting and corrosion undermining paint are a threat to paint integrity and are difficult to stabilize. In such instances environmental control may be the only option guaranteed to prevent ongoing corrosion beneath the paint layer. There are instances where ethical arguments support refinishing the surfaces of cultural objects either to their original specification or to an improved standard in order to offer the best opportunity for longevity. This should not compromise the future interpretation of the object.

Refinishing may be acceptable when there is no original paint layer remaining and replicating an original finish offers significantly increased object longevity. A combination of refinishing and preservation of original surfaces may be adopted in some instances.<sup>83</sup> If the condition of the metal allows, refinishing offers opportunity for highly specified surface preparation. It may also be possible to apply modern paint systems if visual appearance rather than replication of the original recipe is deemed to be the most important interpretive factor. Stripping to the bare metal for repainting should involve minimal loss of the original metal.

##### 4.43.7.2 Refinishing Painted Surfaces

Preparation of historic metal surfaces to receive paint must always minimize loss of metal. Commercial conservation programs often adhere to international

standards for preparing surfaces, such as SSPC, NACE, and Swedish Standards. This offers the client a defined measuring point within the contract of work. Repainting the upper hull of the SS *Great Britain* was justified on the basis of continual repaints during the working life of the ship and the presence of a failing modern paint layer. The hull above the waterline was to be exposed to the British climate and merited the best possible protection from the elements.<sup>25</sup> It was stripped to near white metal (SA2.5) using high pressure water lances (2500 bar) and for weaker areas crushed Australian Garnet (8 bar) in preparation for painting (see [Figure 17](#)). Although this removed several microns of original wrought iron, it was reasoned to be ethical as this thickness of metal would inevitably be lost through future corrosion if preparation was not so stringent. The paint system chosen was typical for creating a durable, long-lived outdoor protective coating on a well prepared surface. A three-phase treatment comprising a 2-pack zinc-rich epoxy primer followed by 2-pack high-build main coat paint system with a urethane UV-resistant topcoat, produced a total paint thickness of 225–250  $\mu\text{m}$ <sup>25</sup> (see [Figure 17](#)). The preferred method of application involved an airless spray at  $207 \times 10^5$  Pa with brushing when the spray could not be used. Life expectancy of this layer with appropriate maintenance is predicted at 15 years.

Often it is not possible to prepare corroded metal surfaces to a high standard. In this instance original lead-based paints are preferred, both to replicate original paint layers and because of their perceived longevity. Since health and safety considerations make their manufacture costly and their use has environmental implications, aluminum-based primers are normally used instead. Ferro zinc (HMG Paints) is a rust conversion paint that was used to paint the monitor HMS *Minerva* after electrolysis.<sup>31</sup> The range of historic alloys and the inability to effectively prepare many surfaces beyond SA 1 or 2 means that each surface offers a unique coating problem. Consequently conservation designs often test paint adherence using a pull-off test (ASTM D 4541-02 or ISO 4624) before applying it to an entire surface. Reports on the longevity of painted surfaces relative to the prepainting condition of the surface and the paint system applied are not reported and this offers another area for research that could act as a platform for designing industry standards. Silanes are used for preparing metals for paint within industry,<sup>70</sup> but this has not been reported in conservation practice.

Where sections of metal have entirely corroded away, decisions regarding a course of action have to

**Figure 17** Surface preparation to SA2.5 standard on the SS *Great Britain* and the completed paint schedule.<sup>25</sup> Images courtesy of Eura Conservation Ltd.

account for ethical, technical, and corrosion considerations. Structural problems require structural solutions but care must be taken not to create galvanic cells by repairing with alloys of differing potential from the original metal. Equally, where structural

**Figure 18** Challenges in metal conservation extend beyond museum interiors to whole sites such as housing at Valparaiso (UNESCO World Heritage site) and abandoned factory settlements like Stromness (South Georgia) whaling station. Images courtesy of Eura Conservation Ltd.

integrity is not a concern it is possible to use glass reinforced plastics and epoxy systems.<sup>25</sup>

#### 4.43.8 Overview

The overall equation for preserving cultural metals is a complex mixture of material science, context, and

ethics. During the past 40 years, conservation has developed links with corrosion science that have led to greater understanding of corrosion processes, which, in turn, supports investigation into treatment mechanisms and methods. This has been extensively boosted over the past 15 years by increased application of modern instrumental analysis in conservation

research. Much greater opportunity exists for collaboration between conservators and corrosion scientists to develop a synergistic relationship for solving the problems of preserving 'metallic heritage.'

Within conservation there are normally multiple preservation options, either due to insufficient evidence to identify one treatment as being significantly better than another or because of differing, but equally valid ethical arguments allow for a range of conservation routes and outcomes. Thus, within this review, large iron chloride-infested naval vessels were treated in four different ways in attempts to stabilize them. HMS Holland was washed in an inhibitive solution to extract chloride<sup>31</sup>; CSS Hunley will be treated by a newly researched washing method employing alkali and pressure<sup>12,28,29</sup>; HMS Minerva was electrolyzed to remove chloride<sup>31</sup>; SS Great Britain used environmental control to prevent corrosion.<sup>11,25,32</sup> All methods are either supported by new research or utilize universally applied treatment techniques. They also have a strong treatment rationale with practical arguments to support the course of action taken. While there will always be diverging views and arguments on appropriate ethical strategies, there remains the opportunity to ensure treatments are researched and optimized. Conservation is a staged process with systematic treatments. There is initially a rationalizing process to decide a course of action, which is then split into treatment stages. As an example, chloride removal from iron might be followed by an inhibitive treatment, over which a coating is applied and the result is subjected to long-term monitoring that assesses outcomes and provides data for future action. Large-scale complex contextual combinations will challenge this approach. At Valparaiso *ad hoc* steel houses form a world heritage site (see Figure 18). They are lived in and offer the challenge of corroding sheet steel, galvanized structures and various paint regimes. Besides finding safe, proven treatment procedures, complex decisions exist on retention of paint, set against a backdrop of what the occupants want and expect, relative to their standard of living. Should the structures eventually become a museum or continue to be lived in? Deserted, but equally daunting, are the remains of a whaling station at Stromness, South Georgia. Remoteness, climate influences, and cost offer significant challenges here. An overarching consideration is climate change and how it will influence corrosion.

Conservation should define standards of preservation, starting with costly indefinite survival of metals down to the guarantee of only a few months

preservation. Developing such a scale goes beyond the science of preservation to its ethics. It may be argued that national icons providing cornerstones in societies merit the cost of indefinite preservation, but commonplace archaeological iron that is to be analyzed, recorded, and published is preserved only for the duration of the analysis and publication process. Counter arguments would focus on the importance of future research into material such as archaeological iron. Suggesting a scale of importance will necessitate extensive ethical debate about how to define importance. In the modern world of diminishing resources, carbon footprints and concern over environmental impact, there are difficult decisions to make and responsibilities to accept for the action taken. Focused coordinated research in collaboration with corrosion scientists can contribute towards informing these decisions for metals preservation.

# Symbols and Abbreviations

## SI Units

<i>SI Base Units</i>	<i>Name</i>	<i>Symbol</i>
Length (l)	metre	m
Mass (m)	kilogram	kg
Time (t)	second	s
Current (I)	ampere	A
Temperature (T)	kelvin	K
Amount of substance	mole	mol
Luminous intensity	candela	cd

<i>Named Derived SI Units [note 1]</i>	<i>Name</i>	<i>Symbol</i>	<i>Relation to SI Base Units</i>
Frequency (Hz)	hertz	Hz	$s^{-1}$
Celsius temperature	degree celsius	$^{\circ}\text{C}$	K
Force (F)	newton	N	$\text{m kg s}^{-2}$
Pressure, stress (P)	pascal	Pa ( $\text{N m}^{-2}$ )	$\text{m}^{-1} \text{kg s}^{-2}$
Energy, work, amount of heat	joule	J	$\text{m}^2 \text{kg s}^{-2}$
Power	watt	W	$\text{m}^2 \text{kg s}^{-3}$
Electric charge	coulomb	C	A s
Electric potential difference	volt	V	$\text{m}^2 \text{kg s}^{-3} \text{A}^{-1}$
Current density	ampere per square metre	$i$	$\text{A m}^{-2}$
Electric resistance (R)	ohm	$\Omega$	$\text{m}^2 \text{kg s}^{-3} \text{A}^{-2}$
Electric conductance	siemens	S	$\text{m}^{-2} \text{kg}^{-1} \text{s}^3 \text{A}^2$
Capacitance (C)	farad	F	$\text{m}^{-2} \text{kg}^{-1} \text{s}^4 \text{A}^2$
Area	square metre	A	$\text{m}^2$
Volume	cubic metre	V	$\text{m}^3$
Density	kilogram per cubic metre	$\rho$	$\text{kg m}^{-3}$
Amount concentration	mole per cubic metre	-	$\text{mol m}^{-3}$

<i>Non-SI Units</i>	<i>Name</i>	<i>Symbol</i>	<i>Relation to SI Units</i>
Volume	litre [note 2]	L, l	$\text{dm}^3$
Concentration	molarity [note 3]	M	$\text{mol d}_m^{-3}$
Concentration	molality	$m$	$\text{mol kg}^{-1}$
Potential	electrochemical potential	E	V
Diffusion	diffusion coefficient	D	$\text{m}^2 \text{s}^{-1}$
Pressure	bar [note 4]	bar	$100 \text{ kN m}^{-2}$
Pressure	atmosphere	atm	$101.325 \text{ kN m}^{-2}$

### Notes

1. This is not a complete listing (the Bureau International des Poids et Mesures is the official source for information on SI units, and readers are referred to their web site at [www.bipm.org](http://www.bipm.org) for further information).
2. The standard SI unit of volume is  $\text{m}^3$  however the litre (Both upper (L) and lowercase symbols are in use although the former is preferred to avoid confusion with the number 1), equivalent to  $1 \text{ dm}^3$ , is in widespread use (and is permitted).
3. The standard SI unit of concentration is  $\text{mol m}^{-3}$  however, molarity (M) is in widespread use although it is deprecated.
4. The standard unit of pressure is  $\text{N m}^{-2}$  (Pa), however 'bar' and 'atmosphere' are in widespread use (although deprecated) especially for reporting of atmospheric air and gas pressures.

**SI Prefixes**

<i>Factor</i>	<i>Name</i>	<i>Symbol</i>	<i>Factor</i>	<i>Name</i>	<i>Symbol</i>
$10^{15}$	peta	P	0.1	deci	d
$10^{12}$	tera	T	0.01	centi	c
$10^9$	giga	G	$10^{-3}$	milli	m
$10^6$	mega	M	$10^{-6}$	micro	$\mu$
$10^3$	kilo	k	$10^{-9}$	nano	n
100	hecto	h	$10^{-12}$	pico	p
10	deca	da	$10^{-15}$	femto	f

**Fundamental Physical Constants**

<i>Symbol</i>	<i>Name</i>	<i>Value</i>
$c$	speed of light in vacuum	$2.99792 \times 10^8 \text{ m s}^{-1}$
$k$	Boltzmann constant	$1.38065 \times 10^{-23} \text{ J K}^{-1}$
$e$	elementary charge	$1.60218 \times 10^{-19} \text{ C}$
eV	electron volt	$1.60218 \times 10^{-19} \text{ J}$
$\epsilon_0$	electric constant (permittivity)	$8.85419 \times 10^{-12} \text{ F m}^{-1}$
$F$	Faraday constant/ The Faraday	$96\,485 \text{ C mol}^{-1}$
$m_u$	atomic mass constant	$1.6605 \times 10^{-27} \text{ kg}$
$N_A$	Avogadro constant	$6.02214 \times 10^{23} \text{ mol}^{-1}$
$R$	molar gas constant	$8.31447 \text{ J K}^{-1} \text{ mol}^{-1}$
$V_m$	molar volume of ideal gas (at STP, see below)	$22.414 \times 10^{-3} \text{ m}^3 \text{ mol}^{-1}$

**Standard Temperature and Pressure**

Standard Temperature and Pressure (STP) for gases, which should not be confused with the standard state (or standard conditions), see below, is defined in a number of different ways:

<i>Temperature</i>	<i>Pressure</i>	<i>Standards authority</i>
0°C / 273.15K	100 kPa	IUPAC <sup>†</sup> – current definition
0°C / 273.15K	101.325 kPa	IUPAC – former definition, NIST – current definition
25°C / 298.15K	100 kPa	NIST – definition for standard atmospheric temperature and pressure (SATP)
20°C / 293.15K	101.325 kPa	Normal Temperature and Pressure (NTP – used in oil and gas industry)

<sup>†</sup> International Union of Pure and Applied Chemistry.

**Standard State**

*Definition from: Compendium of chemical terminology, IUPAC, 2<sup>nd</sup> edition (1997):*

“The state of a system chosen as standard for reference by convention; three standard states are recognized:

- For a gas phase it is the (hypothetical) state of the pure substance in the gaseous phase at the *standard pressure*  $p = p^\circ$ , assuming ideal behaviour.

- For a pure phase, or a mixture, or a solvent in the liquid or solid state it is the state of the pure substance in the liquid or solid phase at the standard pressure  $p = p^\circ$ .
- For a solute in solution it is the (hypothetical) state of solute at the standard molality (i.e.  $\text{mol kg}^{-1}$ )  $m^\circ$ , standard pressure  $p^\circ$  or standard concentration  $c^\circ$  and exhibiting infinitely dilute solution behaviour.

For a pure substance the concept of standard state applies to the substance in a well defined state of aggregation at a well defined but arbitrarily chosen standard pressure.”

The standard state is thus defined as the condition where all chemical species are at a thermo-dynamic activity equal to one and that the total gas pressure is 100 kPa (1 bar). Note that the temperature is not defined and should therefore be specified explicitly.

## Common Suffixes

<i>Suffix</i>	<i>Meaning</i>
<sub>o</sub> (as in $i_o$ )	equilibrium
<sub>a</sub> (as in $E_a$ )	anode/anodic
<sub>c</sub> (as in $E_c$ )	cathode/cathodic
<sub>l</sub> (as in $i_l$ )	limiting
<sub>corr</sub> (as in $i_{corr}$ )	corrosion
<sub>pass</sub> (as in $i_{pass}$ )	passive
<sup>o</sup> (as in $E^\circ$ )	at the standard state
